An Efficient Method for Computing Optical Waveguides With Discontinuous Refractive Index Profiles Using Spectral Collocation Method With Domain Decomposition

Chia-Chien Huang, Chia-Chih Huang, and Jaw-Yen Yang

Abstract—An accurate and efficient solution method using spectral collocation method with domain decomposition is proposed for computing optical waveguides with discontinuous refractive index profiles. The use of domain decomposition divides the usual single domain into a few subdomains at the interfaces of discontinuous refractive index profiles. Each subdomain can be expanded by a suitable set of orthogonal basis functions and patched at these interfaces by matching the physical boundary conditions. In addition, a new technique incorporating the effective index method and the Wentzel–Kramers–Brillouin method for the a-priori determination of the scaling factor in Hermite–Gauss or Laguerre–Gauss basis functions is introduced to considerably save computational time without experimenting with it. This method shares the same desirable property of the spectral collocation method of providing a fast and accurate solution but avoids the oscillatory solutions and improves the poor convergence problem of the simple spectral collocation method with single domain where regions of discontinuous refractive index profiles exist. Applications to several two- and three-dimensional waveguide structures having exact or accurate approximate solutions are given to test the accuracy and efficiency; all the results are found to be in excellent agreement.

Index Terms—Discontinuous refractive index profiles, domain decomposition, optical waveguides, orthogonal basis function, scaling factor, spectral collocation method.

I. INTRODUCTION

RECENTLY, there has been growing interest in developing integrated optics devices in optical communication systems. The fundamental operating principle and optimal design of optical devices such as modulators, switches, filters, fibers, and semiconductor lasers are often based on the comprehension of optical waveguide theory [1]. Hence, solving the optical waveguide problem is an essential way to clearly realize these devices. However, only a limited number of waveguides, which have simple geometry and specific refractive index profiles (RIPs), have analytic solutions [1], [2]. Consequently, employing approximate or numerical methods to obtain propagation characteristics of general waveguides is definitely necessary and of practical importance.

There exist many effective and accurate numerical methods for solving optical waveguide problems. These include the beam propagation method (BPM), [3], [4], finite difference (FD), [5], [6], and finite element (FE) methods [7], which all produce good results. In the past decade, the series expansion method has become very popular and has been widely applied in studying the optical waveguide problems due to its superior accuracy and lower computational storage because of the smaller size of matrix equations required. The spectral collocation method (SCM) [8] (i.e., the collocation method in [9] proposed by Sharma and Banerjee) and the Galerkin method [10] are the two most prevalent methods in series expansion. More recently, many researchers [11]–[15] have successfully implemented the Galerkin method with different orthogonal basis functions to investigate optical waveguides and optical fibers but few pursued SCM. Sharma and Banerjee [9], [16] first applied SCM with Hermite–Gauss (HG) basis functions in propagation characteristics of optical waveguiding structures for two kinds of problems as follows. First, for the waveguide modal problems, SCM attained the same degree of convergence compared with the Galerkin method for given terms of orthogonal basis functions but needed much less computational time, resulting from the avoidance of evaluating laborious integral elements as undertaken by the Galerkin method [16]. Second, the propagation problems using SCM also provided better convergence than BPM [16].

These advantages of SCM produced good results only applicable under the condition of the continuous RIP in interest domain. As for discontinuous RIP, the SCM solutions show the oscillatory phenomenon (the so-called Gibbs phenomenon) and induce difficulty to converge, as illustrated in [16]. Causa et al. [17], [18] also used SCM with HG in some cases, such as longitudinally nonuniform, Kerr-nonlinear media and nonlinear carrier diffusion in semiconductor optical devices. Because of the existence of discontinuous RIP, even though the difference of refractive index between different mediums is small, too many terms of HG still were needed (the number of terms of HG are $N = 99$) to achieve desirable results. As mentioned above, although SCM is powerful and simple, there still exists a major drawback when dealing with the discontinuous RIP

in interest domain. For the solution of a differential equation solved through SCM in terms of a complete set of orthogonal basis functions, the expansion coefficients are determined by requiring the expansion to satisfy the differential equation exactly at certain discrete points, which are the so-called collocation points. Meanwhile, RIP is indicated as an interpolation of the refractive index at these collocation points; therefore, the discontinuous RIP cannot always be described accurately at the discontinuous interfaces. With this notable flaw, the merit of the high accuracy of SCM has not been completely exploited, and it can result in poor convergence due to the existence of discontinuous functions in computational domain [8]. The larger the difference of refractive index at discontinuous interfaces is, the larger the error in describing the actual RIP in SCM may become.

In this paper, our purpose is first to propose SCM with domain decomposition (DD) to deal with the discontinuous RIP in the interest domain, while SCM with only single domain usually produces oscillatory results and poor convergence [16]; second to decide the suitable set of orthogonal basis functions that naturally describes the electromagnetic characteristics at each subdomain; and finally to derive a technique for choosing the scaling factor when using HG or Laguerre–Gauss (LG) basis functions (LGs are usually used in optical fiber of circular structure [19]) avoiding iterative experimenting with it and enhancing the accuracy. By combining these techniques, the accuracy of solution can be significantly improved and the computational time of finding a scaling factor is substantially reduced.

This paper is organized as follows. In Section II, we describe the mathematical formulations of the wave equations. The description of the SCM with DD is stated in Section III. Section IV analyzes in detail the choice of the scaling factor. In Section V, we first compare two cases calculated by Banerjee and Sharma [16] with the results obtained by the present method; then a few examples that include planar and diffused channel waveguides solved by analytical or highly accurate approximate methods are also tested. After that, we discuss the effect of scaling factor. Section VI concludes this paper.

II. MATHEMATICAL FORMULATIONS OF WAVE EQUATIONS

Assuming monochromatic electromagnetic fields with a time dependence of \( \exp(j\omega t) \), propagating along the \( z \)-direction in an inhomogeneous medium with refractive index \( n(x, y, z) \), the vector wave equation can be derived from the Maxwell’s equations for a source free region in frequency domain as follows:

\[
\nabla^2 \vec{E} + k_0^2 n^2 \vec{E} + \nabla \left[ \nabla \frac{n^2}{n^2} \cdot \vec{E} \right] = 0,
\]

Similarly, the vector wave equation based on the magnetic field vector is given by

\[
\nabla^2 \vec{H} + k_0^2 n^2 \vec{H} + \nabla \left[ \nabla \frac{n^2}{n^2} \times (\nabla \times \vec{H}) \right] = 0
\]

where \( k_0 = 2\pi/\lambda_0 \) and \( \lambda_0 \) is the wavelength in free space. Considering the longitudinally (i.e., \( z \)-direction) invariant structure, namely, \( \partial n^2/\partial z = 0 \), the refractive index depends only on the two transverse directions, that is, \( n = n(x, y) \). Here, we are only concerned with the guided mode solutions, with a periodic \( z \)-dependence of the form \( \exp(-j\beta z) \), where \( \beta \) is the propagation constant. When the two polarizations of \( E_x \) and \( E_y \) (or \( H_x \) and \( H_y \)) are weak for three-dimensional waveguides, the coupling terms may be neglected [4]. Hence we can individually deal with the uncoupled equations termed as the semivector [7], [8] or quasi-vector [15] analysis, as follows:

\[
\frac{\partial^2 E_x}{\partial x^2} + \frac{\partial}{\partial x} \left( \frac{1}{n^2} \frac{\partial n^2}{\partial x} E_x \right) + \frac{\partial^2 E_x}{\partial y^2} + k_0^2 (n^2 - n_e^2) E_x = 0 \quad (3)
\]

for the quasi-TE modes and

\[
\frac{\partial^2 H_x}{\partial x^2} - \frac{1}{n^2} \frac{\partial n^2}{\partial y} \frac{\partial H_x}{\partial y} + \frac{\partial^2 H_x}{\partial y^2} + k_0^2 (n^2 - n_e^2) H_x = 0 \quad (4)
\]

for the quasi-TM modes.

Here \( n_e = \beta/k_0 \) is the effective refractive index. The second terms of (3) and (4) are polarization dependence. Furthermore, if the weakly guiding approximation is assumed in the whole interest domain, then we can neglect polarization dependence to obtain the scalar wave equation

\[
\frac{\partial^2 \theta}{\partial x^2} + \frac{\partial \theta}{\partial y^2} + k_0^2 (n^2 - n_e^2) \theta = 0, \quad \theta = E_x, H_x
\]

that considerably reduces the computational time. For three-dimensional (3-D) structures, we only compute a diffused channel waveguide in this paper, which has been solved by Sharma and Bindal [20] assuming scalar approximation. In two-dimensional (2-D) structures such as planar waveguides, the derivatives with respect to \( x \) in (3) and (4) are zero if the infinite extension is along the \( x \)-direction. Hence, we obtain the formulas

\[
\frac{\partial^2 E_x}{\partial y^2} + k_0^2 (n^2(y) - n_e^2) E_x = 0 \quad (6)
\]

for TE modes and

\[
\frac{\partial^2 H_x}{\partial y^2} - \frac{1}{n^2} \frac{\partial n^2}{\partial y} \frac{\partial H_x}{\partial y} + k_0^2 (n^2(y) - n_e^2) H_x = 0 \quad (7)
\]

for TM modes.

III. SPECTRAL COLLOCATION METHOD WITH DOMAIN DECOMPOSITION

In this section, we describe how to solve the optical waveguide problems mentioned previously (5)–(7) by SCM with DD. Apparently, to deal with the inaccurate description of discontinuous RIP at interfaces encountered by SCM with single domain [16], we need to divide the whole domain into a few subdomains at these interfaces. According to the feature of each subregion, we may employ different orthogonal basis functions to expand the optical fields in individual subregion. For the internal regions, whose boundaries are finite, Chebyshev polynomials are the favored choice because of their robustness for nonperiodic structure [8]. For the outer regions, which include semi-infinite boundaries, LGs are adequate due to the mathematical characteristic of the exponentially decay to zero at infinity.

For illustration purposes, we confine our description to planar waveguide structures with the transverse spatial direction \( y \). For
any dependent variable \( \theta(y) \) such as electric field \( E_x(y) \) in (6) or magnetic field \( H_y(y) \) in (7) in each internal region, we expand it by Chebyshev polynomials \( \{T_j(y), j = 0, 1, 2, \ldots, N\} \) with \( y \in [-1, 1] \)

\[
\theta(y) = \sum_{j=0}^{N} c_j T_j(y)
\]

(8)

where \( c_j \) are the expansion coefficients and in each outer sub-domain. We expand it by

\[
\theta(y) = \sum_{j=0}^{N} C_j(\theta(y))
\]

(9)

where \( \{\phi_j(\theta(y)), j = 0, 1, 2, \ldots, N\} \) denotes the LGs, i.e., \( \phi_j(\theta(y)) = \exp(\alpha y^2/2)L_j(\alpha y), y \in [0, \infty), \) and \( L_j(\alpha y) \) is the Laguerre polynomial of degree \( j \). In (9), \( \alpha \) is a scaling factor to be determined and can influence the accuracy for a given number of terms of basis functions (discussed in the next section). The independent variable \( y \) is discretized into \( N+1 \) collocation points \( y_i \) (\( i = 0, 1, \ldots, N \)). An alternative expression is that the dependent field variable \( \theta(y) \) is directly expanded by the cardinal basis functions [8], [21] \( \{C_j(y), j = 0, 1, 2, \ldots, N\} \) and the grid point values of fields at \( N+1 \) collocation points \( \theta_j = \theta(y_i) \) as follows:

\[
\theta(y) = \sum_{j=0}^{N} C_j(y)\theta_j
\]

(10)

where

\[
C_{N+1}(y) = \frac{\psi_{N+1}(y)}{\psi_{N+1}'(y_i)} (y - y_i), \quad 0 \leq j \leq N.
\]

(11)

Here, \( \psi_{N+1}(y) \) is a basis function of order \( N+1 \) and the prime denotes the first derivative with respect to \( y \), \( y_i \) are the collocation points with the conditions \( C_j(y_i) = \delta_{ij} \), where \( \delta_{ij} \) is the Kronecker delta. Thus the computations are operated in physical space \( \theta_j \) instead of in spectral space \( c_j \). The field profiles then can be directly obtained from the unknowns \( \theta_j \) in (10). In this paper, we use the latter form (10) because of the direct obtainment of the field profiles \( \theta_j \). The explicit forms of \( C_j(y) \) for distinct basis functions and collocation points are represented below. For instance, in (11), if we take Chebyshev polynomials as basis functions and Chebyshev Gauss–Lobatto points as collocation points (i.e., the extrema of Chebyshev polynomials together with the endpoints at \( \pm 1 \)) for internal finite subdomains, then we have

\[
C_j(y) = \frac{(-1)^j + 1}{2} T_j(y), \quad y \neq y_j
\]

(12)

where \( T_N(y) \) denotes Chebyshev polynomial of order \( N \), \( c_0 = c_N = 2 \), and \( c_j = 1 \) (\( 1 \leq j \leq N - 1 \)). Correspondingly, for outer infinite (or semi-infinite) subdomains, we take LG, namely, \( \psi_{N+1}(y) = \exp(-\alpha y^2/2)(\alpha y)L_N(\alpha y) \) as the basis functions, and the roots of Laguerre polynomial \( L_N(\alpha y) \) of order \( N \) plus \( y_0 = 0 \) as collocation points to facilitate the incorporation of boundary conditions. We have

\[
C_j(\alpha y) = \frac{e^{-\alpha y^2/2}}{\alpha y L_N(\alpha y)} \frac{\alpha y L_N(\alpha y)}{(\alpha y)} (\alpha y - y_j), \quad y \neq y_j.
\]

(13)

Finally, using HG (i.e., \( \psi_{N+1}(y) = \exp(-\alpha y^2/2)H_{N+1}(\alpha y) \)) as basis functions and the roots of Hermite polynomials \( H_{N+1}(\alpha y) \) of order \( N+1 \) as collocation points, we have

\[
C_j(\alpha y) = \frac{e^{-\alpha y^2/2}}{\alpha y L_N(\alpha y)} \frac{H_{N+1}(\alpha y)}{(\alpha y - y_j)}, \quad y \neq y_j.
\]

(14)

The basis functions are adequate and efficient only for the continuous RIP along transverse spatial directions \( y \) using SCM with usual single domain as illustrated in [16]. Using SCM, we substitute (10), based on either (12) for internal regions or (13) for outer regions, into (6) and (7), respectively. Requiring that (6) and (7) be satisfied at these \( N+1 \) collocation points, these lead to

\[
d^2E_x/dy^2 \bigg|_{y=y_i} + k_0^2(n^2(y_i) - n_e^2)E_x |_{y=y_i} = 0
\]

(15)

and

\[
d^2H_x/dy^2 \bigg|_{y=y_i} - \frac{1}{n^2} \frac{\partial^2 H_x}{\partial y \partial y} \bigg|_{y=y_i} + k_0^2(n^2(y_i) - n_e^2)H_x |_{y=y_i} = 0
\]

(16)

Subsequently, (6) and (7) are transformed into \( N+1 \) algebraic eigenvalues (15) and (16) for each subdomain. We obtain in matrix form

\[
[D][\theta] = k_0^2n_e^2[\theta]
\]

(17)

where \( [D] \) is an \((N+1) \times (N+1)\) square matrix. \( \{\theta_0, \theta_1, \ldots, \theta_N\}^T \) are grid point vectors (eigenvectors), where \( T^T \) denotes the transpose. The elements of matrix \( D \) are

\[
D_{ij} = C_j^{(2)}(\alpha y) |_{y=y_i} + k_0^2n_e^2(\alpha y) \delta_{ij}
\]

(18)

for TE modes and

\[
D_{ij} = C_j^{(3)}(\alpha y) |_{y=y_i} - C_j^{(3)}(\alpha y) \left( \frac{1}{n^2} \frac{\partial^2}{\partial y^2} \right) |_{y=y_i} + k_0^2n_e^2(\alpha y) \delta_{ij}
\]

(19)

for TM modes. In the above formulas, \( C_j^{(n)} \) denotes the \( n \)th derivative of cardinal basis function of degree \( j \) with respect to \( y \). The numerical examples of planar waveguides in this paper are mainly based on (18) and (19).

After expanding different basis functions in internal and outer subdomains, we need to employ the boundary conditions of electromagnetic field at these interfaces \( y_k \), \( \{k = 1, 2, \ldots, r\} \), where \( r \) is the number of discontinuity, between different dielectric constants to patch these subdomains as follows:

\[
E_x(y_k^+) = E_x(y_k^-), \quad \frac{\partial E_x(y_k^+)}{\partial y} = -\frac{\partial E_x(y_k^-)}{\partial y}
\]

(20)
for TE modes and
\[ H_x(y_k^+) = H_x(y_k^-), \quad n^2(y_k^-) \frac{\partial H_x(y_k^-)}{\partial y} = n^2(y_k^+) \frac{\partial H_x(y_k^+)}{\partial y} \]  
(21)

for TM modes. Here, \( y_k^+ \) and \( y_k^- \) are referred to the locations at the infinitesimally right and left of the interface \( y_k \), respectively. As a result of special care taken to treat the discontinuity of RIP using DD, the discontinuous RIP in interest domain can be correctly represented and the oscillatory solution in usual SCM with single domain can be efficiently eliminated.

Considering the three-dimensional waveguide structures, the dependent variable \( \theta(x, y) \) in any subdomain is expanded by a product of two separable basis sets \( \Theta(x) \) and \( \Psi(y) \) as follows:

\[ \theta(x, y) = \sum_{j_x=0}^{N_x} \sum_{j_y=0}^{N_y} \Theta_{j_x}(x) \Psi_{j_y}(y) \theta_{j_x,j_y} \]  
(22)

where \( \Theta_{j_x}(x) \) and \( \Psi_{j_y}(y) \) denote two cardinal basis functions of order \( j_x \) along \( x \)- and \( y \)-directions, respectively, and \( \theta_{j_x,j_y} = \Theta_{j_x}(x) \Psi_{j_y}(y) \) now are grid point values in two transverse directions. Using the similar procedures as mentioned above, after substituting (22) into (5), \((N_x+1) \times (N_y+1)\) algebraic eigenvalue equations are obtained.

IV. CHOICE OF SCALING FACTOR

An important point to note is that any orthogonal basis function for an infinite interval implicitly contains a scaling factor \( \alpha \) to set the extension of the mapping, such as HG or LG [8]. Thus reasonably choosing \( \alpha \) can substantially reduce the requiring number of basis functions and evade many additional trial computations with it. In SCM, the scaling factor \( \alpha \) is usually picked up through trial and error with additional expense of a considerable amount of computational time for a given number of terms of the basis functions [16]. Hence a definite way to determine the optimum value of the scaling factor is thus very desirable and necessary. For given terms of basis functions \( N \), \( \alpha \) decides the spread and the extent of collocation points in the transverse direction. In general, there exists an adequate \( \alpha \) for a given \( N \) in optical waveguide problems.

In this paper, we adopt techniques from Tang [22] and Ramanujam et al. [23] and combine them to offer a new novel approach for determining \( \alpha \) for HG and LG. In [22], Tang proposed an interesting and definite procedure to choose \( \alpha \) for Gaussian-type functions that is expanded by the first \( N+1 \) HG of order \( N \) using the expression of series coefficients as given by (9) in spectral space. Here, another approach, which is based on the expression given by (10) in physical space, is used. A more convenient and direct expression than those given in [22] may be derived to obtain an appropriate \( \alpha \). For any dependent variable \( \theta(y) \) in outer regions, we use \( C^\alpha_j(y) \) as basis functions. For Chebyshev polynomials used for internal regions, because of the finite interval of \( y \in [-1,1] \), no scaling factor is provided to adjust. In contrast to HG or LG, \( \alpha \) can be independently accommodated in each outer region. We write

\[ \theta(y) = \sum_{j=0}^{N} C^\alpha_j(y) \theta(y_j) \]  
(23)

where \( \theta(y_j) = \theta_j, 0 \leq j \leq N \), are the grid point values as in (10). At each collocation point \( \{y_j\}_j=0^N \), we obtain

\[ \theta(y_j) = \sum_{j=0}^{N} C^\alpha_j(y_j) \theta_j, \quad 0 < j < N \]  
(24)

which is equivalent to

\[ \theta(y_j) = \sum_{j=0}^{N} C^\alpha_j(y_j) \frac{\theta_j}{\alpha}, \quad 0 < j < N. \]  
(25)

For the HG basis functions, \( \{y_j\}_j=0^N \) are the zeros of \( H_{N+1}(y) \) with the order \( y_0 < y_1 < \ldots < y_N \), while for LG, \( \{y_j\}_j=0^N \) are the zeros of \( L_N(y) \) plus \( y_0 = 0 \). When solving the differential equations, the \( n \)th derivatives of dependent variable \( \theta(y_j/\alpha) \) with respect to \( y \) are also needed and are expanded by

\[ \theta^{(n)}(y_j/\alpha) = \sum_{j=0}^{N} \alpha^n C_j^{(n)}(y_j) \theta_j, \quad 0 < i < N \]  
(26)

where \( C_j^{(n)}(y_j) \) \( (0 \leq j \leq n, 0 \leq i \leq N \) is the so-called \( n \)th differentiation matrix (DM) [24] of the given basis functions. Suppose that the function \( \theta(y_j/\alpha) \) has a finite support \([-M,M]\), i.e., \( \theta(y_j/\alpha) \sim 0 \) for \( |y_j/\alpha| > M \). Thus \( \theta(y_j/\alpha) \) has sufficient contribution to \( \theta(y_j/\alpha) \) in (25) or \( \theta^{(n)}(y_j/\alpha) \) in (26) under the condition

\[ \left| \frac{y_j}{\alpha} \right| \leq M, \quad \text{for all } 0 \leq j \leq N. \]

Accordingly, the following relation determines the scaling factor \( \alpha \) associated with given \( N \) terms

\[ \alpha = \max_{0 \leq j \leq N} \left\{ \frac{y_j}{M} \right\}. \]  
(27)

The above choice of the scaling factor is due to Tang [22], which he originally applied to known Gaussian-type functions. However, the value for the finite support \( M \) in Tang’s work was assumed to be given by a simple truncation of infinite domain into a finite support. In [23], a novel technique has been proposed in Galerkin method with trigonometric basis functions (the Fourier method) for a-priori determination of the finite support (or numerical window in [23]) of the Fourier method by using the Wentzel–Kramers–Brillouin (WKB) method and effective index method (EIM). Here we adopt this technique to determine \( M \) for \( \alpha \) in (27) in our SCM with DD.

According to the character of guided modes in optical waveguide theory [1], the mode shapes of all guided modes oscillate within the core and exponentially decay beyond the turning point. For step-index waveguides, the turning point of all guided modes locates at the same discontinuous interface that is between the outermost and its adjacent layers. As for graded index waveguides, the turning point of each guided mode locates on the different position, where the refractive index is equal to the effective index. If we can obtain the effective index of the highest guided mode, the turning points and the decay rates then can be estimated. Indeed, the characteristic of the optical field is to extend to infinity; thus, we have to set a criterion to decide...
the finite support $M$ beyond which the field strength is sufficiently small and can be neglected. For diffused waveguides, Hocker and Burns [25]–[27] have used WKB method to treat the diffused planar waveguides and combined EIM and WKB to extend to the 3-D diffused channel waveguides.

Suppose we have the following 2-D RIP:

$$n^2(x,y) = \begin{cases} n_m^2 - n_c^2 & \text{if } y \leq 0, -\infty < x < \infty \\ n_c^2 & \text{if } y > 0, -\infty < x < \infty \end{cases} \quad (28)$$

where $n_c$ is the substrate index, $n_m$ is the maximum index at $(x = 0, y = 0)$, and $n_c$ is the cover index. The functions $f(y/D)$ and $h(2x/W)$ are the normalized profiles of the graded index. Here $D$ and $W$ are the parameters of diffusion depth in $y$- and $x$-direction, respectively. First, we use the EIM for the profile in the $y$-direction at each position $x$ and define the normalized guide depth $V(x)$ and effective index parameters $b(x)$ [27] as follows:

$$V(x) = k_0 D \sqrt{n_m^2 - n_c^2} h(\frac{2x}{W}) \quad (29)$$

and

$$b(x) = \frac{n_c(x)^2 - n_s^2}{(n_m^2 - n_c^2) n_c(x)} h(\frac{2x}{W}) \quad (30)$$

where $n_c(x)$ is the effective index, which depends on $x$. Then for a specified value of $x$, employing the WKB theory, we can find $b(x)$ by the dispersion relation [26, (10)] as follows:

$$2V(x) \int_{\eta}^{\eta_0} \sqrt{f(\eta) - b(x)} d\eta = \left(2p + \frac{1}{2}\right) \pi + 2 \tan^{-1} \left(\frac{b(x) + a(x)}{1 - b(x)}\right) \quad (31)$$

where $\eta = y/D$, $\eta_0 = y_k/D$, and $y_k$ is the turning point, which satisfies $f(y_k/D) = b(x)$ at a given $x$; and $p = 0, 1, 2, \ldots$, denotes the order of mode along the $y$-direction. Once we have $b(x)$, we can obtain $n_c(x)$ at each $x$ through (30). Here, the phase shift at the turning point ($y = y_k$) is $-\pi/2$, and that at the interface of air and material ($y = 0$) is $-2 \tan^{-1} \sqrt{b(x) + a(x)/(1 - b(x))}$. As shown in [26], $a(x)$ denotes the asymmetry index for a given $x$, and its value is variant for TE ($a_{TE} = (n_s^2 - n_c^2)/(n_s^2(x) - n_c^2)$) and TM ($a_{TM} = (n_s^2(x)/n_c^2)((n_s^2(x) - n_c^2)/(n_s^2(x) - n_s^2))$) modes, $n_s^2(x) = n_c^2 + (n_m^2 - n_c^2) h(2x/W)$. A set of data $(x, n_c(x))$ then can be obtained point by point through the repeated computations from (29)–(31), and the equivalent planar waveguide to the original channel waveguide can be represented by the symmetric index profile $n_c(x)$ along the $x$-direction. The normalized guide depth $V$ and effective index $\tilde{b}$ of the equivalent planar waveguide can be defined by

$$\tilde{V} = k_0 W \sqrt{n_m^2(0) - n_s^2} \quad (32)$$

and

$$\tilde{b} = \frac{(n_c)^2 - n_s^2}{(n_m^2(0) - n_s^2)} \quad (33)$$

where $n_c$ is the effective index of the original channel waveguide and $n_c(0)$ denotes the value of the symmetric effective index profile $n_c(x)$ at $x = 0$. Apply the WKB method again to the $x$-dependent RIP $n_c(x)$. The dispersion relation equations [27, (18)] determining $\tilde{b}$ for the equivalent symmetric planner waveguides are as follows:

$$\tilde{V} \int_{0}^{\eta_0} \sqrt{h(\rho(b) x) - \tilde{b}} d\rho = \left(q + \frac{1}{2}\right) \pi \quad (34)$$

where $\rho = 2x/W$, $\rho_0 = 2x/W$, $x_t$ is the turning point in $x$-direction, which satisfies $h(2x_t/W) = \tilde{b}$, and $q = 0, 1, 2, \ldots$ represents the mode number along the $x$-direction. Once we have obtained $\tilde{b}$, $n_c$ can be determined by (33) and $x_t$ is calculated through $h(2x_t/W) = \tilde{b}$. Using the same definition as [23], we denote the decay rates for the mode as

$$\gamma_{gc}(y_0) = k_0 \sqrt{n_s^2 - n_c^2} \quad (35a)$$

$$\gamma_{gs}(y) = k_0 \sqrt{n_c^2 - n_s^2(0, y)} \quad (35b)$$

$$\gamma_{gs}(x) = k_0 \sqrt{(\tilde{n}_c)^2 - n_s^2(x)} \quad (35c)$$

Accordingly, we can estimate the decay rates of optical fields $\gamma_{gc}$ along the $y$-direction into cover and substrate sides, respectively, and $\gamma_{gs}$ is along the $x$-direction into substrate. For determining the finite support or numerical window $M$, we need to specify a criterion to assume that the field strength at $M$ is much less than the field strength at turning points. Moreover, the ratio of the field strength at $M$ relative to the field strength at turning points has to be adequately and reasonably decided. If the ratio is too small, then the spreading we calculate is too wide to reduce computational time and the number of the basis function. Contrarily, the large ratio represents the field strength at $M$ may not be negligible. In this paper, following Ramanujam et al. [23], we take the ratio as 0.01. Hence, to find the finite support in each direction, we first let

$$\frac{E(\Delta y_k)}{E(0)} = \exp \left[ -\int_{0}^{\Delta y_c} \gamma_{gc} dy \right] = 0.01 \quad (36a)$$

$$\frac{E(y_k - \Delta y_s)}{E(y_k)} = \exp \left[ -\int_{y_k}^{y_k - \Delta y_s} \gamma_{gs} dy \right] = 0.01 \quad (36b)$$

$$\frac{E(x_t + \Delta x_s)}{E(x_t)} = \exp \left[ -\int_{x_t}^{x_t + \Delta x_s} \gamma_{gs} dx \right] = 0.01 \quad (36c)$$

as indicated in Fig. 1, and determine $\Delta y_c$, $\Delta y_s$, and $\Delta x_s$ from (36a)–(36c). Then the finite support along $x$-direction is $M_x = [x_t + \Delta x_s]$. For the $y$-direction, $M_y = [y_k + \Delta y_s]$ and $M_y = [y_k + \Delta y_s]$ are the finite supports along cover and substrate sides, respectively. We want to emphasize here that the a-priori choice of the numerical window only needs the roughly approximate values, because the main function of scaling factor $\alpha$ in HG or LG is to redistribute the collocation points corresponding to $\alpha = 1$ (no scaling) to more efficiently describe the field profiles. Thus the tolerance of $M$ may not be so strict.

After that, we can adjust the density of collocation points by choosing suitable $\alpha$ and concerning more collocation points near the regions where the field values change explosively. It
Fig. 1. Illustration of modal profiles for the cross-sectional view of a diffused channel waveguide having symmetric and asymmetric graded index profiles along $x$- and $y$-directions in (a) and (b), respectively. In (a), the dotted lines represent the location of the turning points at $x_t$, $\gamma_{xs}$ is decay rate, and $x_t + \Delta x_s$ is position of spreading for a given mode. For (b), the turning points are at zero and $y_t$, where $\gamma_{ys}$, $\gamma_{yc}$ denote decay rates and $y_t - \Delta y_s$, $\Delta y_c$ are spreadings for substrate and air sides, respectively.

is noted that in [23], the numerical window is used in Galerkin method with trigonometric functions. Due to the characteristics of trigonometric basis set, the boundary conditions at infinity of optical field cannot be satisfied; hence the requirement to decide numerical window is severe and the accuracy strongly depends on the parameter $M$. In the present method, the HG or LG can automatically satisfy the boundary conditions at infinity and no enclosed window is needed. Indeed, the a-priori choice of scaling factor can substantially reduce the computational time and efficiently improve the convergence.

V. NUMERICAL RESULTS AND DISCUSSION

We first discuss two numerical examples in detail that allow the existence of discontinuous RIP in interest domain, as studied in [16], to demonstrate the significant improvement of convergent behavior of effective refractive index using DD and the a-priori choice of scaling factor in SCM. Second, to examine the accuracy of this method, several waveguides are investigated, including asymmetric graded index waveguide, which possesses high-order modes, metal-clad waveguide, planar directional coupler, and diffused channel waveguide. Finally, we discuss the effect of scaling factor.

A. The Fundamental Mode of Slab Waveguide for Symmetric Step Index and Asymmetric Graded Index Profiles in [16]

We study two examples that have been solved by Banerjee and Sharma in [16]. The first example is a three-layer symmetric step-index slab waveguide (see Fig. 2), which supports single mode. The refractive indexes of core and claddings are $n_c = 1.45$ and $n_{cl} = 1.44736$, respectively. The half-width of the core is $W = 3\mu m$, and the optical wavelength is $\lambda = 1.3\mu m$. We divide the whole domain into three subdomains at the two interfaces of discontinuous RIP as indicated in Fig. 2. Region I is expanded by Chebyshev polynomials, because of the finite boundary; however, region II and region III are both expanded by LG due to the semi-infinite extension in each region. Using the transcendental equation of TE mode for three-layer step-index waveguide [2] to find the effective index, and according to (35) and (36), the decay rates and spreadings are then obtained. Here, we have the spreadings $M_{II} = 15.77\mu m$ and $M_{III} = 15.77\mu m$ for the two outer regions II and III, respectively. In Table I, $N_I$, $N_{II}$, and $N_{III}$ represent the number of terms of orthogonal basis functions in each region. We first fix $N_I$ and simultaneously adjust $N_{II}$ and $N_{III}$ because of the symmetry. When $N_I = 3$, the convergent mode value only achieves $1.448978$ no matter how many terms of $N_{II}$ and $N_{III}$ are used. After increasing to $N_I = 5$, the result nearly converges to the exact solution $1.44890$ associated with $N_{II} = N_{III} = 5$. After that, $\alpha_{II} = \alpha_{III} = 0.596$ (namely, scaling factors for region II and region III, respectively) can be evaluated by (27). Comparing to the results of [16, Table 4], which were obtained using $N = 40\rightarrow 68$ terms of HG in single domain, our solutions obviously eliminate the oscillatory phenomenon and can achieve the exact solution using merely 15 terms of orthogonal basis functions altogether.

The second example is an asymmetric graded index profile slab waveguide as depicted in Fig. 3(a). Here, the RIP is a Gaussian profile described as follows:

$$n^2(y) = \begin{cases} n_s^2 + 2n_s\Delta n \exp(-\frac{y^2}{2\sigma^2}), & y \geq 0 \\ \frac{n_s^2}{n_c^2}, & y < 0 \end{cases}$$

(37)

where $n_s = 1.512$, $n_c = 1.0$, $\Delta n = 0.0833$, and $d = 2.06\mu m$ at $\lambda = 0.6328\mu m$. The interest domain is divided into two subdomains, and we obtain the spreadings $M_I = 0.38\mu m$ for region I and $M_{II} = 3.06\mu m$ for region II, which are calculated by the WKB method (through (29)–(31) at $x = 0$). In [16], only the fundamental mode of the example is solved. Even though the number of the terms of HG is up to $N = 50$ in usual single domain, the effective index seems to have difficulty in convergence. Similar to the first example, we set $N_I = 4$ and increase the number of $N_{II}$ to 8. The exact result is attained with a total of 12 terms of LG, as given in Table II. At the same time, $\alpha_I = 16.55$ and $\alpha_{II} = 6.34$ are determined. From these two examples, we can see the superior convergence of the present method and its ability to completely exclude oscillatory solutions. Meanwhile, the a-priori choice of scaling factor has
been implemented. Otherwise, more computational effort must be spent, if determined through trial and error.

B. The High-Order Modes of Asymmetric Planar Waveguide With Exponential RIP

To investigate optical waveguides, including high-order modes is also important in precisely designing many devices such as multimode fiber and multimode interference used in dense wavelength-division multiplexing (DWDM). For examining the accuracy for high-order mode problems, we solved an asymmetric slab waveguide with exponential RIP, as shown in Fig. 3(b), which supports eight TE and TM modes. The exact solutions have been obtained in [28]. The RIP is described as follows:

\[ n^2(y) = \begin{cases} 
  n_s^2 + 2n_c \Delta n \exp(-\frac{y}{d}), & y \geq 0 \\
  n_c^2, & y < 0 
\end{cases} \quad (38) \]

where \( n_s = 2.47 \) is the substrate index, \( n_c = 1.0 \) is the cover index, \( \Delta n = 0.06 \) is the maximum index change, \( d = 2.5 \mu m \) is the depth of diffusion, and \( \lambda = 0.633 \mu m \) is the wavelength, respectively. The interest domain is divided into two subdomains. In our calculation for TE modes, the spreadings are \( M_I = 0.21 \mu m \) and \( M_{II} = 26.44 \mu m \). The number of LG in region I is \( N_I = 5 \) and in region II is \( N_{II} = 25 \), for which \( \alpha_I = 45.74 \) and \( \alpha_{II} = 3.08 \) are obtained. Likewise, for TM modes, \( M_I = 0.21 \mu m \) and \( M_{II} = 27.26 \mu m \) are calculated, \( N_I = 5 \) and \( N_{II} = 25 \) are used, and we have \( \alpha_I = 45.74 \) and \( \alpha_{II} = 2.99 \). The exact [28] and approximate [29] solutions of effective indexes of TE and TM modes together with ours are listed in Table III. In addition, the results of TM modes solved by expanding both the index profile and modal field into a Fourier series [30] are also added in. There were a few modifications for the exact effective indexes [28] calculated by Noro and Nakayama displayed in [29] using the characteristic equations \([28, (8) \text{ and } (13)]\) for TE and TM modes, respectively. Most of the data are correct, but the third order (\( m = 2 \)) and the sixth order (\( m = 5 \)) of TM modes show slight deviation. We recalculated them using secant method, and found that the effective index of the third order is 2.486 660 2 and sixth order is 2.473 250 7. After rounding off all the data of effective indexes, the values are shown in Table III.

The present method achieves better accuracy than [29] and [30], which used $N = 400$ terms of Fourier series, and shows the indistinguishable result with exact solution within 30 terms of LG. Fig. 4 shows the mode profiles of modes 0 (solid line), 4 (dashed line), 7 (dotted line) of TE by exact method [28] and our solutions (filled circles); they are all in excellent agreement. From the results of this case, our method can accurately provide the effective indexes and mode profiles for optical waveguide modes simultaneously, even when they support higher order modes.

C. The Metal-Clad Optical Waveguides

We have illustrated the accuracy obtained by our method for lossless optical waveguides in above cases. Here, the SCM with DD is extended to analyze the lossy optical or the so-called metal-clad optical waveguides. The metal-clad waveguides provide many applications in integrated optics devices, for example, polarizers and mode filters. Many researchers have investigated the metal-clad waveguides theoretically and experimentally for step index [31], [32] and graded index profiles [33]–[35]. In this case, we solve the exponential RIP like case B but the refractive index $n_2^2$ is replaced by the complex refractive index $n_2^c$, as illustrated in Fig. 5. This problem has been studied by an analytical, highly accurate numerical method in [33] and by a Galerkin method with trigonometric basis functions in [35]. The profile is given as follows:

$$n_2(y) = \begin{cases} n_2^2 \left[ 1 - 2\Delta(1 - \exp(-y/a)) \right], & y \geq 0 \\ n_2^m, & y < 0 \end{cases} \quad (39)$$

where the waveguide index parameters are $n_2^2 = 2.29592$, $n_2^m = -10.3 - i$, the gold cladding, and $a$ is the depth of diffusion at the wavelength $\lambda = 0.6328 \mu m$. Regions I and II in Fig. 5 are both expanded by LG. Because of the difficulty of finding the spreading of the imaginary part of the optical field in advance, we only consider the real part of $n_2^c$ to approximately calculate the spreading of the real field of the highest mode by WKB [(35) and (36)]. Although this idea is not rigorous, the small error is acceptable for the approximate prediction of spreading due to the fact that the spreading of real fields is close to the imaginary fields, as illustrated by [32, Fig. 7]. In addition, because the difference of refractive indexes at the interface ($x = 0$) of metal and surface of material is large (i.e., $n_2^2 - \text{Re}(n_2^m) = 12.59592$), the phase shift at $x = 0$ may be assumed as $-\pi$ [25], [26]; thus we obtain the same values of spreadings of TE and TM modes. Accordingly, the spreadings of the highest mode ($m = 2$) are $M_1 = 0.13 \mu m$ in region I and $M_2 = 15.54 \mu m$ in region II. We used $N_1 = 5$, $N_2 = 12$, $\alpha_I = 72.27$, and $\alpha_II = 2.86$ for $a = 5 \mu m$.

In Table IV ($a = 5 \mu m$), our solutions still show highly accurate results as compared with the accurate numerical solutions in [33] no matter whether the real or image part of propagation constants is encountered. Here, the total number of terms of LG in the present method is within 20. In [35] (only TE modes were solved), even using $N = 300$ Fourier series, the solutions were still inferior. This case exhibits that the optimal scaling factors ($\alpha_I = 72.27$ and $\alpha_II = 2.15$) are extremely hard to achieve through trial and error. Furthermore, through the DD, the scaling factor can be independently determined in each subdomain; unlike SCM applied in single domain, $\alpha$ is the same in the whole computational domain and is chosen in flexibly. Hence, the convergence for our method is achieved more quickly than SCM using only single domain.

D. The Planar Directional Coupler

A directional coupler is an interesting optical device that often is used as a beam splitter, filter, optical switcher, etc. Due to the wide applications in optical communications, it is necessary to understand how a directional coupler works. In general, the
simplest directional coupler consists of two parallel slab waveguides, as shown in Fig. 6. When a directional coupler is used as an optical switcher, the modulation fields in the two waveguides (located in regions II and III in Fig. 6) are usually applied with an equal amount of electric field but with opposite sign to change refractive indexes due to the electrooptic effect $\Delta n$ of crystals, resembling lithium niobate (LiNbO$_3$). The refractive index of the right waveguide (region III) is then increased by $\Delta n/2$ and decreased by $\Delta n/2$ in the left waveguide (region II). Generally, $\Delta n$ is often a tensor quantity for anisotropic medium, but here, only an isotropic change of refractive index is considered. The widths of the two waveguides are $W = 2 \mu m$. For the zero modulation fields at wavelength $\lambda = 1.06 \mu m$, the refractive indexes of the two waveguides are $n_c = 2.2$. The separation between the guides is $s = 1.85 \mu m$. Except the guides, the refractive indexes are everywhere. Here, we divide the whole domain into five subdomains at these discontinuous interfaces. The spreadsings calculated in regions IV and V are obtained by regarding the guides as isolated (i.e., weakly coupled approximation) in this structure. However, the spreadsings we obtained are $M_{IV} = M_{V} \approx 5 \mu m$ for all the different $\Delta n$ due to the weakly coupled approximation, which are calculated by the same dispersion relation for a three-layer step index waveguide as adopted in the first example in case A. If the coupling is strong, we need additional analysis to evaluate the spreading. The optical fields under three various refractive indexes induced by different modulation fields $\Delta n = 0.0000, \Delta n = 0.0008, \Delta n = 0.0020$ are illustrated in Fig. 7(a)–(c), respectively. In Fig. 7(a)–(c), the real lines and dashed lines represent the even and odd modes, respectively. Under variant applied fields, the induced change of refractive indexes $\Delta n$ is indicated in Table V, and the propagation constants of the even ($\beta_e$) and odd ($\beta_o$) modes calculated by the present method using 31 basis functions altogether are exact compared with analytical solutions and the solutions obtained by finite element method [36] using 4000 mesh divisions. Here, we used seven Chebyshev polynomials in regions I, II, and III ($N_I = N_{II} = N_{III} = 7$) and five LG in regions IV and V ($N_{IV} = N_{V} = 5$). The present method can be straightforwardly extended to some devices containing anisotropic and layered waveguide structures.

E. The Diffused Channel Waveguide

In the last case, this method is extended to investigate diffused channel waveguide, which is formed by diffusing titanium ($T_{i}^{2+}$) into LiNbO$_3$ in x- and y-directions and hence produces graded RIP. The RIP is given by (28), where $n_r^2 = n_s^2 + 2n_s \Delta n$, $f(y/D) = \exp(-y^2/2D^2)$, and

$$h \left( \frac{2\pi}{W} \right) = \frac{\text{erf} \left( \frac{W}{2\sqrt{2D(1+\frac{\pi}{16})}} \right) - \text{erf} \left( \frac{W}{2\sqrt{2D(1-\frac{\pi}{16})}} \right)}{2\text{erf} \left( \frac{W}{2\sqrt{2D}} \right)}. \quad (40)$$

Here, erf denotes error function and the parameters are $D = 3.35 \mu m$, $W = 6.0 \mu m$, $n_s = 2.203$, $n_c = 1$, wavelength $\lambda = 1.3 \mu m$, and $V = h_0(W/2)\sqrt{2n_s\Delta n}$ is the normalized frequency. Sharma and Bindal [20] listed a few results solved by scalar variational analysis using different trial fields, and the solutions obtained by [37] were acclaimed as the most accurate variational analysis by them. We tested our method using scalar

Fig. 8. The cross-sectional view of general diffused channel waveguide divided into two regions at the interface of $y = 0$, where $n(x, y)$ is diffused refractive index profile along $x$- and $y$-directions.

wave (5) to this case and divided the computational domain into two subdomains, region I ($y \geq 0$) and region II ($y \leq 0$), as illustrated in Fig. 8.

In (22), the optical field along the $x$-direction is expanded by HG due to the continuous RIP, and the $y$-directions in region I and region II are individually expanded by LG due to the discontinuous RIP the same as previous cases. The spreading obtained are $M_{gc} \simeq 0.48 \mu m$ for different values of $V$, which are nearly the same $M_{gs} = 11 - 19 \mu m$ and $M_{es} = 11 - 27 \mu m$ for $V = 3.179 - 2.119$, respectively. For the case $V = 3.179$, the spreading $M_{gs} = 11.5 \mu m$, and $M_{es} = 11.3 \mu m$, the convergence is obtained by using $N_{gc} = 4$ ($\alpha_{gc} = 12.98$) terms of LG for region I along $y$-direction into cover, $N_{gs} = 10$ ($\alpha_{gs} = 2.3$) terms of LG for region II along $y$-direction into substrate, and $N_{es} = 13$ ($\alpha_{es} = 0.36$) HG along $\pm x$-direction. The cross-section of modal profile at $x = 0$ for the case $V = 3.179$ calculated by this method is plotted in Fig. 9, and the characteristics of rapid decay in the interface (as illustrated by the dashed line in Fig. 9) between air and the surface of material can be seen. Our solutions of normalized propagation constants $b = [(\beta/k_0)^2 - n_s^2]/2n_a\Delta n$ versus $\nu$ compared with results in [20] are shown in Fig. 10. We can see that our results are closer to the results in [37] than those obtained by evanescent secant hyperbolic (ESH) or secant hyperbolic (SH) trial fields. The propagation constants can be efficiently and accurately obtained because the spreadings solved by WKB and EIM yield good approximation with actual optical fields, as depicted in Fig. 9.

Finally, we note that for all the cases studied in this section, we have used the a-priori choice of scaling factor $\alpha$ in HG or LG.
for optical waveguide problems and obtained efficient convergence to effective indexes. In principle, $\alpha$ decides the extension of collocation points. Hence, for a given number of terms of basis functions, if $\alpha$ is chosen too small, the too-sparse density of collocation points is used to accurately describe the modal profiles, which change explosively. In contrast, if $\alpha$ is too large, the narrower distribution of collocation points cannot properly take into account the contribution of long extension of higher order modes. In some previous works, using Galerkin method with HG [13], [15] or with LG [19] for step index or truncated parabolic optical fibers, a fixed value of the scaling factor $\alpha_G = \sqrt{\frac{b_0}{a_1^2}}$ was chosen, where $n_1$ is the refractive index of the core, $n_2$ is the index of cladding, and $a$ represents the radius of the core for step index circular fiber or is half the width of channel waveguides. However, for asymmetric diffusion waveguides of general profiles, this scaling factor $\alpha_G$ cannot be assigned for the region 1 in Fig. 3(a) and (b) or Fig. 5 due to the indefinite parameter $a$. Accordingly, the a-priori determination of $\alpha$ by the present method not only can be used in step index or symmetric graded index waveguides but also can be used in asymmetric graded index waveguides.

VI. CONCLUSION

We have proposed an efficient solution method that combines spectral collocation method and domain decomposition for computing optical waveguides with discontinuous refractive index profile. Through domain decomposition, one can flexibly expand different basis functions in distinct subdomains depending on the extension of each region. In addition, we have presented a new approach to choose the scaling factor to optimally determine the spreading of the highest guided mode of optical waveguides by combining Tang’s work [22] and the technique proposed by Ramanujam et al. [23]. The major factor to improve the convergence is to divide the whole domain into a few subdomains at the interfaces of discontinuous refractive index profile to enable that interpolation of the refractive index at these collocation points can faithfully represent the discontinuous refractive index profile. Consequently, the oscillatory solutions obtained by spectral collocation method with usual single domain [16] can be completely eliminated and the degree of convergence can be improved. Moreover, the a-priori choice of scaling factor in Hermite–Gauss or Laguerre–Gauss functions materially reduces the computational time without trial and error. Merging these two techniques, namely, the domain decomposition and the optimal choice of scaling factor, into conventional spectral collocation method renders the present solution method both accurate and efficient. Our results have demonstrated significant improvement of convergence over the solutions obtained using usual single domain for spectral collocation method. A wide range of waveguide problems has been tested, such as planar, metal-clad, directional coupler, and diffused channel waveguides, and all the results obtained are found in excellent agreement with exact or other best available accurate approximate solutions. Also, significant saving of computational time has been illustrated. For the three-dimensional channel waveguide, only scalar wave equation is solved here. However, this method can be further extended to semivector or full-vector formulas [4] for investigating more complicated devices, which require the polarization dependence and coupling terms to be considered.

Extension of this method of full-vectorial modal analysis of dielectric waveguides will be reported elsewhere.
