InAsN/InGaAs single quantum wells (SQWs) with different nitrogen concentration have been successfully grown on InP substrates by gas source molecular beam epitaxy used rf plasma nitrogen source. Photoluminescence (PL) results of the as-grown samples show red-shifted PL peak energy and rapidly degraded intensity as the nitrogen concentration increases. The roughly estimated maximum nitrogen mole fraction in these samples is 0.4%. Both the PL intensity and linewidth of these InAsN/InGaAs SQWs were significantly improved after postgrowth rapid thermal annealing with the optimum temperature at 525–550 °C for samples with different nitrogen content. The improvement on 10 K PL intensity can be as high as 230 times, and the room temperature PL intensities of the annealed InAsN SQWs have been comparable to those of InAs SQWs used for laser diodes. Quantum well intermixing (QWI) induced blue-shifted PL spectra were also observed in these samples. The QWI threshold temperature decreases as the nitrogen concentration increases, which indicates that defects created by nitrogen incorporation may enhance the QWI. © 1999 American Vacuum Society. I. INTRODUCTION

Low nitrogen content zincblende III–V alloys have received much attention in the past few years. The large difference in atomic sizes and electronegativities of N and As has motivated the theoretical approach to understand the huge bowing parameter and also to ascertain the semiconductor or semimetal nature of these alloys. In addition, the large conduction band offset of these materials is very promising to overcome the poor temperature characteristics of conventional InGaAsP/InP system long-wavelength laser diodes. Recently, Kondow et al. reported InGaAsN grown on a GaAs substrate for a light-emitting material having a band gap suitable for long-wavelength laser diodes at 1.3 μm. Tu et al. also demonstrated InAsN grown on a InP substrate for 1.55 μm laser diodes. Both alloys are very important for an optical communication system.

In the midinfrared 2–5 μm wavelengths, InAsN alloy could also be a very promising material. Recently, we demonstrated high-quality 2.2 μm InAs/InGaAs/InP highly strained multiquantum well lasers grown by gas-source molecular beam epitaxy (GSMBE). Using InAsN to replace InAs can ease the design limitation on quantum well thickness and decrease the band gap of quantum well. It reveals the possibilities of pushing laser emission to longer wavelength. However, there are still no definitive results on the growth of InAsN alloy. Beresford et al. had studied these alloys grown by plasma-source molecular beam epitaxy. They reported that InAsN alloy phase is metastable and forms in a fairly narrow temperature window of approximately 450–500 °C. At higher temperatures or higher group V supersaturations, only separated phases of InAs and InN are observed. So far, there is still not any optical property data available. On the other hand, postgrowth thermal annealing is used to improve the quality of low nitrogen content III–V alloys. Rao et al. and Francoeur et al. had studied the postgrowth thermal annealing in GaAsN bulk materials. In this article, we demonstrated the InAsN/InGaAs SQW grown on InP substrates by GSMBE and studied the influence of postgrowth rapid thermally annealing treatments on their photoluminescence properties.

II. EXPERIMENT

The samples were grown on semi-insulating (100) InP substrates using a VG V-80H GSMBE system. Element In, Ga, and thermally cracked AsH3 and PH3 sources were used. An EPI UNI-bulb rf plasma source operated at a radio frequency of 13.56 MHz was used to generate active N species or H species. The rf power for generating N species was 300 W. After the thermal cleaning of the InP substrate at 500 °C the rf plasma source was switched immediately to N2 gas under P2 flux, the brightness mode H2 plasma was first ignited and a 0.1-μm-thick InP layer was then grown as a buffer layer at 450 °C. Some reports indicated that atomic hydrogen can enhance the removing of surface oxide and passivate some impurities and defects. Then, the growth was interrupted and the substrate temperature was reduced to 400 °C for InGaAs/InAs(N)/InGaAs SQW growth. The SQW structure layer is comprised of two 100-nm-thick In0.53Ga0.47As barriers and a 30-Å-thick InAs(N) well. The growth rate for InAs(N) was 1 μm/h. There were no inter- or intraquantum well at the heterointerfaces of the SQW. The gas line of the rf plasma source was switched immediately to N2 gas when the growth of the first SQW interface was starting. During the gas switching, the plasma still maintained high brightness mode. The rf power was turned off when the growth of the SQW was finished. The beam equivalent pressure (BEP) of the N source during the growth of InAsN...
SQW was around $10^{-5}$ to $10^{-4}$ mbar, depending on the nitrogen flow rates. The BEP data of samples are summarized in Table I. Finally, a 0.1-μm-thick InP cap layer was overgrown on the SQW.

The annealing was performed using a ULVAC D91906 rapid thermal annealer. Before annealing, a spin-on silica capping layer was coated on the samples and baked at 400 °C for 30 min in air so as to prevent the desorption of the group V elements. We fixed the annealing time at 15 min and changed the annealing temperature from 500 to 650 °C. Typical temperature fluctuation of this annealer was within 10 °C. The optical quality was evaluated using PL measurements. The 488 nm line of an argon laser was used as the excitation source and a closed cycle helium cryostat was used for low temperature measurements. The signal was detected using a liquid nitrogen cooled InSb photodiode with a Hamamatsu P3357-02 preamplifier. X-ray spectrum measurements were performed using Bede QC1A double crystal x-ray diffractometer.

### III. RESULTS AND DISCUSSION

The 10 K PL spectra of the as-grown samples are shown in Fig. 1(a). As can be seen, the PL peak energy decreases with increasing nitrogen flux. This result indeed confirms the bowing effect due to the incorporation of nitrogen. However, the PL intensity degrades very rapidly with the increasing of nitrogen concentration, and the full width at half maximum (FWHM) also has similar behavior. Figure 1(b) shows the room temperature PL spectra of these as-grown samples. No room temperature luminescence can be detected in our PL system for samples C, D, and E. These results indicate the presence of high concentration nonradiative centers. Since there is a very large atomic-size difference between N and As (0.75 vs 1.20 Å), the large local strain from the nitrogen incorporation in InAs crystal could result in inferior crystallinity. However, it could also be partially caused by the low growth temperature. In general, the more the N atoms incorporated into InAs, the worse the sample crystallinity, and the weaker the PL intensity. All of the behaviors are similar to those reported previously for the (In)GaAsN system. X-ray diffraction (XRD) spectra of these samples were also measured. However, the 30-Å-thick InAs(N) quantum well is too thin to make a difference between the spectra of the samples with and without nitrogen. XRD simulation results also support this point.

The 10 K PL spectra of InAs SQW, sample A, before and after annealing for 15 min from 500 to 650 °C are illustrated in Fig. 2(a). As can be seen, the postgrowth annealing leads to higher PL intensity and sharper FWHM. The PL peak position (~0.63 eV) shows only a slight blue-shift below 650 °C. As the annealing temperature rises to 650 °C, the PL peak position displays a significant blue-shift and the FWHM also increases. This is due to quantum well intermixing (QWI). The Ga atoms from the barriers diffuse into QW and increase the band gap energy of QW. The integrated PL intensity and FWHM are plotted against the annealing temperature in Fig. 2(b). Basically, the increase of the annealing temperature only results in slight improvements on the PL properties. The optimum temperature is around 600–625 °C. Because of the good as-grown quality of sample A, the improvement is not remarkable.

![Fig. 1. PL spectra of as-grown InAs(N)/InGaAs SQW at 10 K (a) and at room temperature (b).](image-url)
On the other hand, there are very different behaviors for InAsN SQW samples with the same postgrowth annealing process. Figure 3(a) shows the 10 K PL spectra of sample E before and after 15 min annealing with different temperatures from 500 to 575 °C. As can be seen in Fig. 3(a), the postgrowth annealing leads to higher PL intensity and sharper FWHM. The improvement is very significant compared with the pure InAs SQW, i.e., sample A. The PL peak position (~0.57 eV) also shows almost no shift for the annealing below 575 °C. As the annealing temperature rises to 575 °C, a noticeable blue-shift on the PL peak energy is observed. The PL peak intensity also degrades significantly, even smaller than that of the as-grown sample. However, the FWHM does not increase. The integrated PL intensity and FWHM as functions of annealing temperature are plotted in Fig. 3(b). Below 575 °C, the increase of annealing temperature results in improvements both on the PL intensity and FWHM. The optimum temperature is around 525–550 °C. Other InAsN SQW samples, i.e., samples B, C, and D, all show very similar behaviors as those of sample E. Among them, sample C has the most significant improvement on 10 K PL intensity. The integrated intensity after annealing is about 230 times of that of before annealing. The detailed results of these samples are summarized in Table I. These results indicate that postgrowth annealing can effectively reduce the number of the nonradiative defects in the InAsN SQWs.

Compared with the pure InAs SQW, i.e., sample A, the red-shift of sample E due to nitrogen incorporation is about 60 meV. Kondow et al. reported that the band gap shrinkage coefficient of strained InGaAsN is 150 meV per nitrogen concentration in percent. Francoeur et al. reported that the band gap reduction of GaAsN with a nitrogen mole fraction of ~3% is 400 meV. According to these experimental results, the roughly estimated nitrogen mole fraction of sample E is around 0.4%.

The threshold temperature of QWI decreases when the nitrogen concentration increases, as can be seen in Table I. Basically, the incorporation of nitrogen atoms into the InAs quantum well deteriorates the crystallinity and increases the density of defects. These defects may enhance the QWI and...
decrease the threshold temperature, which is consistent with the previous QWI studies on other compound alloys.\footnote{B. S. Ooi, Y. S. Tang, A. S. Helmy, A. C. Bryce, J. H. Marsh, M. Paquette, and J. Beauvais, J. Appl. Phys. 83, 4526 (1998).}

Figure 4 shows the room temperature PL spectra of all InAs\textsubscript{N} SQW samples after annealing at their optimum temperature. As can be seen, the PL intensity of InAs\textsubscript{N} SQWs are improved after the postgrowth annealing. The after annealing PL intensities of samples C and D have especially been comparable with that of sample B and their peak intensities are just one-third of that of sample A, the InAs SQW, whose intensity is very closed to those of our previous laser devices.\footnote{R. Beresford, K. S. Stevens, and A. F. Schwartzman, J. Vac. Sci. Technol. B 16, 1293 (1998).}

Notice that the room temperature luminescence of samples C and D are not observable before annealing, as can be seen in Fig. 1(b). Furthermore, the temperature dependence PL spectra of all samples have the same behaviors and show only one peak. This result indicates again that the emission is from the direct recombination across the band gap but not due to the deep level of InAs.

IV. CONCLUSION

In summary, we have successfully grown InAs\textsubscript{N}/InGaAs SQW on InP substrates by GSMBE using a rf plasma nitrogen source. The poor as-grown optical quality of InAs\textsubscript{N} SQWs can be significantly improved with postgrowth annealing, and the optimum annealing temperature is about 525–550 °C for samples with various nitrogen contents. According to the red-shifted energy of the PL emission peak, the roughly estimated maximum nitrogen concentration is around 0.4%. The defects enhance the QWI and reduce the threshold temperature of QWI. Combining the optimum growth condition and postgrowth annealing, InAs\textsubscript{N} SQWs with device quality have been obtained.
