Porous NiSi-Si composite particles having homogeneously distributed intraparticle pores with the size distribution peaked at 200 nm and a porosity of ~40% have been synthesized by a novel method, which comprises steps of ballmilling induced reaction to form NiSi/Si preform particles and subsequent dissolution of unreacted Ni. Upon lithiation/delithiation cycling, the composite particle electrode exhibits much reduced thickness expansion and capacity fading rate, as compared with the pure Si particle electrode. The improvements have been attributed to the success in introducing the preset voids to partially accommodate volume expansion arising from Si lithiation. In situ synchrotron XRD further indicates that NiSi of the composite is active toward Li alloying, and it undergoes reversible transformation to/from Ni2Si and Li5Si. The reversible transformation between the silicides involves volume change in opposite to lithiation of Si, and is beneficial to stabilizing the composite electrode upon charge/discharge cycling.© 2006 The Electrochemical Society. Graphite is widely used as an anode material for commercial lithium-ion batteries due to the advantages of low cost, low and flat working voltage, and excellent reversibility. However, the disadvantage is relatively low theoretical capacity, ~370 mAh/g (or 830 Ah/L). The recently announced Sony Nexelion battery adopts tin-based amorphous anode material consisting of multiple elements, such as tin, cobalt, and carbon, which are mixed on a nanometer level. Compared with graphite anode, the lithium ion storage volumetric capacity in Nexelion is increased by 50%, which increases the overall battery capacity by 30%.

Seeking anode materials of even higher capacities, much effort has been carried out and elaborated worldwide on silicon-based material. As an anode material for Li rechargeable batteries, Si has a theoretical capacity greater than 3000 mAh/g. However, dramatic volumetric variations, >300%, upon discharge/charge and poor electronic conductivity hindered its application. A thin-film type of Si anode, prepared mainly by vacuum sputtering has been demonstrated to exhibit up to 200 cycles at more than 3000 mAh/g, by either tailoring the microstructures of the film and film-substrate interfaces or using films of amorphous Si-containing alloys. Less success has, however, so far been achieved with the conventional thick-film particulate electrode configuration.

One approach to enhancing the cycle life of the Si-based thick-film electrode is to combine Si with a highly conductive secondary material to form a composite.6-14 This secondary material, which can be either electrochemically inactive or active toward Li alloying, is thought to “buffer” between Si particles for enhancing the stability of the electrode structure during cycling, and concurrently to enhance the overall conductivity of the electrode. The extent of improvement, nevertheless, varies widely, apparently depending heavily on the microstructure and composition of the Si-containing composite.

Previous research had suggested the importance of a porous structure on the dimensional stability of the electrode. The structural design of a loosely packed small particle matrix, for example, was shown to result in significant improvement on cycle stability of a Sn/SnSb anode.15 In this work, a systematic and viable approach is capable of introducing homogeneously distributed ‘‘preset’’ voids into the Si anode matrix is introduced. Specifically, NiSi-Si composite powder was synthesized in a way that it contains a significant fraction of intraparticle voids with dimensions in the nanometer range and a porosity of ~40%. The electrochemical properties of the composite electrode were characterized by cyclic voltammetry (CV) and charge/discharge (C/D) cycling test, while the electrode expansion effect was also studied by means of electrochemical dilatometry. In addition, the electrochemical Li alloying/ dealloying processes were studied by in situ X-ray diffraction (XRD), and the resolved lithiation mechanism of NiSi turns out to be completely different from what previously suggested.6,7

Experimental

Alloy powders were synthesized by mechanically alloying mixtures of appropriate amounts of high purity elemental powders of Si (99%, ~325 mesh, Aldrich) and Ni (5 μm, CERAC). The mechanical alloying was performed with a planetary mill (Fritsch Pulverisette P7) under Ar atmosphere using stainless steel vials and balls. The weight ratio of ball:powder is 14:1, and 0.5 wt % of stearic acid [CH2(CH2)16COOH] was added as a lubricating agent. After milling at 400 rpm for 16 h, an intermediate phase of Ni/Si/NiSi composite was formed. The resulting powder was put in 0.5 M HNO3 for 1 h to etch off Ni. The amount of Ni dissolved in the etching solution was determined by inductively coupled plasma (ICP) spectrometry (Optima 3000XL). The powder was finally washed and dried in a vacuum oven at 50°C for 6 h.

The composite electrode consists of, on a dry basis, 62 wt % NiSi-Si composite, 30 wt % conductive additives, and 8 wt % binder. The binder was a mixture of styrene-butadiene-rubber (SBR; L1571, Asahi Chemicals) and sodium-carboxyl-methyl-cellulose (SCMC; WS-C, Cellogen, DKS International, Inc.) with 1:1 weight ratio.15 The conductive additives included graphitic flakes (KS6, 3 μm, TIMCAL) and nanosized carbon black (Super P, 40 nm, TIMCAL) with a weight ratio of 5:1. The mixed-slurry was coated on Cu-foil with a final film thickness of ~50 μm. CR2032 coin cells were fabricated from the electrode for electrochemical characterizations. The pure Si electrode has been prepared the same way. The counter electrode was lithium foil. The electrolyte was 1 M LiPF6 in ethylene carbonate (EC):ethyl methyl carbonate (EMC) (1:2 vol %) from Mitsubishi. In the adopted two-electrode setup, the voltage referred to herein is measured against the Li counter electrode.

CV analysis was performed between 0.05 to 3.0 V at 10 mV/min. The charge/discharge (C/D) tests were carried out with a constant current-constant voltage (CC-CCV) mode within the volt-
The NiSi alloy started to appear after a milling time of 10 h, while the peaks of Ni were no longer detected after a milling time of 48 h (Fig. 2). Throughout the milling process, NiSi was the sole product detected. Thus, the formation of NiSi by the ballmilling process basically follows a one-step reaction mechanism

\[ \text{Ni} + \text{Si} \rightarrow \text{NiSi} \]  

For preparing the electrode, the powder after 16 h of milling was etched in diluted HNO₃ solution to remove the unreacted Ni. The purpose of the etching step is to increase the overall intraparticle porosity of the composite powder. The XRD patterns of power before and after the etching treatment are shown in Fig. 3.

The in situ synchrotron XRD was conducted in the National Synchrotron Radiation Research Center (NSRRC) in Taiwan. The energy of synchrotron radiation is 13 keV ($\lambda = 0.9537$ Å). The measurement of in situ dilatometry was carried out during lithium uptake/extraction to monitor the thickness changes of the electrode. The principle of dilatometric measurement has been described in Ref. 16.

**Results and Discussion**

**Synthesis and micro-structural characterization.**—The as-received Si powder has a size distribution that peaks at $20 \mu$m (curve a, Fig. 1) and contains $77 \%$ of particles with a size between 10 and 40 $\mu$m. Figure 2 shows the XRD patterns acquired after different periods of milling. Note that the peaks representing the NiSi-Si composite particles are constituted of numerous submicrometer components.

Electrochemical characterization.— The CVs for the first five cycles of the NiSi-Si electrode are shown in Fig. 6a, while those of the fifth cycle for Si and the composite electrode are compared in Fig. 6b. For the composite, the response current increases with cycle number. A similar phenomenon has also been observed for the pure Si electrode, and the increase is believed to largely arise from a break-up of particles to provide a larger surface area and thus better kinetics for material utilization. The trace profile, nevertheless, became unchanged after the fifth cycle. For the composite electrode, the reductive (alloying) reaction onsets at 0.8 V and the current continues to increase exhibiting a peak at ~0.15 V. On the other hand, the Si electrode shows a reductive reaction commencing below ~0.3 V. During the oxidative (dealloying) process, the composite electrode shows a broad hump extending up to 1.0 V, while the Si electrode shows distinct peaks below 0.6 V. The data indicates that the alloying/dealloying processes of the composite electrode, which contains both NiSi and Si, involves additional redox reactions taking place within higher potential regions to those associated with pure Si.

The cycling capacity data of the Si and NiSi-Si composite electrodes are displayed in Fig. 7, while the charge/discharge voltage curves of the composite electrode are shown in Fig. 8. For the electrode containing pure Si, the first discharge capacity reached ~3300 mAh/g (the capacity data referred to herein are based on unit weight of active material, which is either Si or the NiSi-Si composite), but suffers from 62% loss upon charge. The dischargeable capacity quickly dropped to ~200 mAh/g in 5 cycles. At the same current density (0.1 A/g or 0.33 mA/cm²), the NiSi-Si composite electrode showed much improved cycling stability. It exhibited an initial discharge capacity of 1250 mAh/g and ~13% loss upon charge. The coulombic efficiency quickly reached ~99% at the second cycle.

bonds: charge.

is either Si or the NiSi-Si composite. The capacity data are based on unit weight of active material, which

tively (e.g., Fig. 9a for Si). After 10 cycles, the thickness of the pure Si electrode (Fig. 9b) expanded to 200 μm, while the composite electrode expanded to 96 μm (Fig. 9c). In situ dilatometric analysis (Fig. 10) further showed that, for both cases, the electrode expansion took place mainly during the first cycle, and the thickness variations during the subsequent cycles were much milder than that during the first cycle. This may explain, at least in part, why the irreversible capacity loss is most dramatic during the first cycle and died down rapidly upon further cycling, as shown in Fig. 7.

In situ synchrotron XRD study. — The XRD patterns acquired in situ during discharge and charge are shown in Fig. 11a, while the corresponding discharging and charging voltage curves marked with the locations where spectra were acquired are shown in Fig. 11b for reference. As typically occurs during the first discharge, the voltage rapidly dropped to below 0.1 V. Several events were found to occur concurrently then. First, the reflection peaks of graphite [e.g., C(002) in Fig. 11a] shifted to lower angles, suggesting lattice expansion due to Li intercalation. Second, the intensities of Si peaks [e.g., Si(111) in Fig. 11a] decreased with discharge depth, and peaks completely disappear at the depth of ~980 mAh/g. The intensity reduction is apparently due to the alloying with Li to form amorphous Li0.3Si. The same process has been reported in the literature for the pure Si electrode.7 Third, the intensities of NiSi [e.g., NiSi(2110)] followed the same trend as Si, decreasing gradually with increasing discharge. Finally, a new nickel silicide phase, δ-Ni2Si, emerged and its peak intensities increased with increasing discharge.

Upon charge, the events described above were reversed except that the Si peaks remain amorphous and hence undetectable. NiSi reappeared after charging. This is contradictory to the previous suggestion by Wang et al.,6 that the silicide phase irreversibly separated into Si and Ni upon the first discharge. No analysis, however, has been given in their study.

Taking into account both the electrochemical characterization and in situ XRD data, the following two sets of alloying reactions are proposed for the NiSi-Si composite system. For the NiSi component

\[ x\text{Li}^+ + xe^- + \text{NiSi} \rightleftharpoons \text{Li}_x\text{NiSi} \quad 0.3 \sim 1.0 \text{ V} \]  

\[ 2\text{Li}_x\text{NiSi} + (y - 2x)\text{Li}^+ + (y - 2x)e^- \rightleftharpoons \text{Li}_y\text{Si} + \text{Ni}_x\text{Si} \quad < 0.3 \text{ V} \]  

and for the Si component

\[ y\text{Li}^+ + ye^- + \text{Si} \rightleftharpoons \text{Li}_y\text{Si} \quad < 0.3 \text{ V} \]  

Equation 2 accounts for the redox reactions taking place within the high voltage region (between 0.3 and 1.0 V) as observed in the voltammograms of the composite electrode (Fig. 6). In addition, the XRD data upon discharge (Fig. 11a) showed that the Ni2Si peaks were detected only during the very later stage of the diminishing of NiSi peaks, suggesting that Ni2Si may not form in one step from NiSi. Thus, two sequential alloying reaction steps, Eq. 2 and 3, are proposed. The alloyed Li0.3NiSi species is likely to be amorphous, similar to the alloyed Si, and hence no intermediate was detected.

Assuming the y value in Reaction 3 corresponding to Li15Si4 gives the theoretical gravimetric capacity of 579 mAh/g for NiSi and 1298 mAh/g for the present NiSi-Si composite powder. Taking
into account of the theoretical density, 4.35 g/cm³, of the composite (molar ratio NiSi:Si = 1:1) gives the volumetric capacity of 5646 mAh/cm³ for 100% dense powder or 3389 mAh/cm³ for the powder with 40% porosity. For comparison, the gravimetric and volumetric capacities for the graphite are ~370 and 833 mAh/cm³, respectively. For either gravimetric or volumetric capacity consideration, the present porous powder shows apparent advantage.

Furthermore, the amount of Si that participates in charging/discharging in the composite electrode is 2/3 of that in the pure Si electrode, yet the extent of electrode expansion for the composite electrode is merely ~1/3 that of the pure Si electrode. The difference indicates that the preset void has indeed served the purpose to

partially accommodate the volume expansion arising from the Si component, and that the reduced thickness expansion in the composite electrode is more than a “dilution” effect, i.e., reduction in Si content per unit volume. It is also worth mentioning that Ni$_2$Si has a density (7.315 g/cm$^3$) higher than that of NiSi (5.928 g/cm$^3$). Thus, the volume shrinkage of the silicide phase could also compensate the volume expansion of the Si component.

Many new anode materials have been proposed in the literature and only a few of them will finally find application after all optimization work has been done. The structural design of our nanoporous NiSi-Si composite in this study has yet to be optimized. The characteristics of final structures, including surface morphology, porosity, and pore size distribution, depend on several synthesis parameters, such as the experimental condition of milling process, etching time, the ratio of Si/Ni, and so on. It is believed that refinement of these parameters can further improve the cycling stability.

Conclusions

In this study, porous NiSi-Si particles having a pore size distribution peaked at 200 nm and an intraparticle porosity of nearly 40% have been synthesized by high-energy ball milling of a mixture of Ni and Si and subsequent dissolution of unreacted Ni. When used as an anode for Li ion battery application, the preset intraparticle voids have been shown to help to accommodate volume expansion arising from alloying of the Si component. As a result, the composite electrode exhibits much reduced thickness expansion, as compared with pure Si electrode, and hence significantly reduced capacity fading rate upon cycling. Synchrotron XRD further indicates that the NiSi component of the composite undergoes reversible transformation to Ni$_2$Si and Li$_x$Si during cycling, which is previously not considered mechanism of this material.
