Long-Term Sustainability of a High-Energy, Low-Diversity Crustal Biome

Li-Hung Lin,^{1,2*} Pei-Ling Wang,³ Douglas Rumble,⁴ Johanna Lippmann-Pipke,⁵ Erik Boice,⁶ Lisa M. Pratt,⁶ Barbara Sherwood Lollar,⁷ Eoin L. Brodie,⁸ Terry C. Hazen,⁸ Gary L. Andersen,⁸ Todd Z. DeSantis,⁸ Duane P. Moser,⁹ Dave Kershaw,¹⁰ T. C. Onstott¹

Geochemical, microbiological, and molecular analyses of alkaline saline groundwater at 2.8 kilometers depth in Archaean metabasalt revealed a microbial biome dominated by a single phylotype affiliated with thermophilic sulfate reducers belonging to *Firmicutes*. These sulfate reducers were sustained by geologically produced sulfate and hydrogen at concentrations sufficient to maintain activities for millions of years with no apparent reliance on photosynthetically derived substrates.

Most subsurface microbial ecosystems examined to date (including subseafloor sediments, deep-sea hydrothermal vents, terrestrial sedimentary aquifers, and petroleum reservoirs) ultimately depend on sunlight. These studies have been mostly confined to depths of less than 1 km, and the ecosystems are either supported by photosynthetically produced electron donors and acceptors transported by groundwater or seawater with ages much less than a million years, or are in constant contact with oxygenated seawater migrating through the underlying fractured basaltic aquifer (1–4). Although two occurrences of autotrophic microbial communities have been reported to exist in <300-m-deep volcanic aquifers flushed with fresh meteoric water (5, 6), their long-term sustainability on H₂ and isolation from photosynthetically produced substrates have not been demonstrated. Although the existence of subsurface microorganisms at depths greater than 1 km in pristine environments is well established (7), much is still unknown regarding the abundance, diversity, and sustainability of these microbial communities over geological time scales.

To determine the long-term sustainability of a deep terrestrial environment, we examined the microbial diversity and metabolic activity of a 3- to 4-km-deep fracture in the 2.7-billion-year-old Ventersdorp Supergroup metabasalt, in which fracture water ages of tens of millions of years (8), abundant abio-

genic hydrocarbons (9), and radiolytically produced H₂ (10) have been reported. To characterize the indigenous microbial composition and its principal respiratory pathway, we analyzed 16S ribosomal DNA (rDNA)

sequences, aqueous and gas geochemistry, and stable and noble gas isotopic signatures of moderately saline groundwater emanating from a fracture zone 2.825 km below the land surface (kmbls) in the Mponeng gold mine, South Africa. This high-pressure water-bearing fracture was intersected during exploratory drilling ahead of a tunnel advancing into an unmined zone ~100 m above the Ventersdorp Contact Reef (VCR) ore zone. The fracture water was initially sampled as soon as it was safe to do so (4 days after the fracture intersection), and three subsequent samples were obtained over a 54-day interval (Table 1) to monitor drilling contamination and possible changes of community structure and geochemistry as the fracture was de-watered and before being sealed by the mine's cementation team.

Fracture water samples yielded a uniform community structure dominated by a single phylotype (MP104-0916-b1) that constituted

*The concentrations derived from charged balance were 10.2 mM for sample 1, 27.6 mM for sample 3 and 50.6 mM for sample 4. †The concentrations of dissolved gases were reported as concentrations corrected for diffusive loss (8). Diffusive correction was not applied to sample 4 because of the lack of noble gas analysis. ‡The positive O₂ content for sample 1 may be derived from incomplete isolation of fracture water from the mining environment caused by the extremely high water pressure and flow rate. §The carbon isotopic value was referenced to Pee Dee belemnite (PDB). ||The uncertainties for aqueous and gas chemistry are ±10% and ±20%, respectively. The uncertainties for isotopic measurements are ±0.5‰ for δ¹³C-hydrocarbon and ±5‰ for δ²H-hydrocarbon and δ²H-H₂.

Fig. 1. Phylogenetic trees for bacteria (A) and archaea (B) based on 16S rDNA sequences recovered from fracture and mining water in the Mponeng gold mine, South Africa. The fraction number in parentheses represents the number of clones for each phylotype versus the total number of clones analyzed in each sample. The scale bar is equivalent to the sequence variation of 10%.

>88% of the clones in the 16S rDNA libraries we generated but did not appear in the water used for mining (Fig. 1A). This phylotype was related (96% similarity) to an uncultured clone recovered from thermal fluids of oceanic crust (11) or to *Desulfotomaculum kuznetsovii* (91% similarity) (12), a sulfate reducer growing at moderately thermophilic conditions. Of the other minor bacterial and archaeal phylotypes associated with the fracture water, MP104-1109-a19 resembled (98% similarity) environmental clones (the SAGMEG-2 group) obtained from fracture water in an adjacent mine (13) (Fig. 1B). Other phylotypes were closely related (98 to 99% similarity) to environmental clones recovered from surface environments (such as soils and sludge) or to various mesophiles distributed within *Proteobacteria*, *Firmicutes*, and *Methanobacteria* (Fig. 1). These minor phylotypes did not resemble those from the mining water [see supporting online material (SOM)].

High-density 16S rDNA microarray analysis was also used as a more sensitive approach to assess microbial diversity. Array hybridization results supported the finding that microbial diversity was much less (table S2) and the *Firmicutes* were of greater relative abundance (table S3) in the fracture water than in the mining water. Some overlap between the sequences found in the fracture water and those in the mining water is expected because mining water is a mixture of recycled fracture water and surface water.

The geochemistry of the fracture water was characterized to identify its origin and to assess the principal metabolic pathways (Table 1 and tables S1 and S4). Over the observation period, the temperature decreased from >60° to 52°C, while the pH was constant and the redox potential (E_h) increased from -330 to -263 mV. The Cl^- , Br^- , and SO_4^{2-} concentrations increased significantly, whereas other anion concentrations fluctuated or decreased slightly. Reduced gases (H_2 and CH_4) were abundant (>1 mM), and their

concentrations increased as water flow rates declined and gas flow rates remained constant. Formate and acetate concentrations ranged from 7 to 9 μM and 22 to 36 μM , respectively. The $\delta^2\text{H}$ and $\delta^{13}\text{C}$ of the abundant dissolved C_{1-4} hydrocarbons indicated an abiogenic origin, based on their similarity to abiogenic hydrocarbon gases identified at other Precambrian Shield sites (9). The $\delta^2\text{H}$ and $\delta^{18}\text{O}$ values of the fracture water, -29.1 per mil (‰) and -6.9‰ VSMOW (Vienna standard mean ocean water), respectively, plotted slightly above the global and local meteoric line (14). The $\delta^2\text{H}$ - H_2 values ranged between -680 and -690‰ VSMOW, which when compared with the $\delta^2\text{H}$ - H_2O value yielded isotopic equilibrium temperatures of 62°C for the first sample, declining to 49°C for the last sample. Based on the thermal conductivity model (15) and the heat flow data (16), the initial temperature equates to that at 4.2 kmbls and the final temperature to that at 2.9 kmbls.

Noble gas analyses yielded elevated radiogenic and fissiogenic concentrations of ^4He , ^{40}Ar , ^{134}Xe , and ^{136}Xe (table S1) but exhibited no systematic trend during the observation period. The bulk model age of the fracture water ranged from 15.8 ± 7.9 million years to 25.0 ± 3.8 million years (Table 1). This model age represents either the true subsurface residence time or the mixing between a hydrothermal fluid that is ancient (0.8 to 2.5 billion years old); saline; and H_2 -, C_{1-4} hydrocarbon-, and SO_4^{2-} -rich; and paleometeoric water that is ~3 to 4 million years old; moderately saline; and H_2 -, C_{1-4} hydrocarbon- and SO_4^{2-} -poor (SOM).

The exceptional dominance of the *Firmicutes* clones; $\delta^2\text{H}$ and $\delta^{18}\text{O}$ values of the fracture water that are distinct from those of the mining water (17); and increasing H_2 , CH_4 , He , Cl^- , Br^- , and SO_4^{2-} concentrations during the observation period suggest that the fracture environment favors the survival of these *Firmicutes*-related microorganisms and that mining operations had minimal impact on this environment during depressurization

and dewatering. *Desulfotomaculum*-related environmental clones and isolates have been detected in other subsurface environments, including an oil reservoir (18), deep sedimentary strata (19, 20), an ore deposit (21), and saline water emanating from a 3.2-kmbls borehole located 13 km east of this borehole (22). The evident success of these microorganisms may not be surprising because their ability to form endospores would facilitate their survival during periods of low water activity, nutrient deprivation, and suboptimal temperature (23). Whether the less abundant members of the clone libraries represent indigenous microorganisms that are capable of acquiring energy through metabolisms that are distinct from those of the strains they most resemble phylogenetically, or alternatively represent moribund relics of shallower, less saline paleometeoric water that has mixed with this fracture water, is not known.

Sulfur isotopic analyses yielded $\delta^{34}\text{S}$ values of HS^- ranging from 11 to 13‰ Vienna Canon Diablo meteorite (VCDT) and those of SO_4^{2-} from 19 to 26‰ VCDT (table S4). The depleted $\delta^{34}\text{S}$ value of HS^- relative to that of SO_4^{2-} (-7.7‰ for sample 4 and -12.4‰ for sample 7) is consistent with microbial sulfate reduction. The fact that SO_4^{2-} concentrations in the fracture water were higher than that of the overlying dolomitic aquifer (13), and that SO_4^{2-} has been reported in analyses of fluid inclusions from hydrothermal quartz in the VCR (24) and the reservoir mixing-fractionation model (SOM), all suggest that the SO_4^{2-} originated from the ancient hydrothermal fluid, not the paleometeoric end member. The $\delta^{34}\text{S}$ values of fracture pyrite (0 to 2‰ VCDT) were less than that of the coexisting barite (10.1‰ VCDT) (table S4) and were consistent with those of hydrothermal 2.0-billion-year-old pyrite from the VCR in the same mine (25). The $\Delta^{33}\text{S}$ values for all samples clustered around 0‰ (table S4). To reproduce the $\Delta^{33}\text{S}$ of total dissolved S species (-0.022‰) for sample 7, a mixing of SO_4^{2-} derived from

*The calculation for maximum substrate consumption rate and steady-state free-energy flux is shown in SOM. †The HS^- concentration used in the calculation for sulfate reduction for samples 1 and 3 were assumed to be 1.3 mM. The free energy for sulfate reduction only varied less than 5% when HS^- concentration was changed between 1.1 to 1.5 mM. ‡The reactions for free energy calculations were as follows: H_2 -sulfate reduction: $4 \text{H}_2 + \text{H}^+ + \text{SO}_4^{2-} \rightarrow \text{HS}^- + 4 \text{H}_2\text{O}$; acetate-sulfate reduction: $\text{CH}_3\text{COO}^- + \text{SO}_4^{2-} \rightarrow 2 \text{HCO}_3^- + \text{HS}^-$; H_2 -methanogenesis: $4 \text{H}_2 + \text{H}^+ + \text{HCO}_3^- \rightarrow \text{CH}_4 + 3 \text{H}_2\text{O}$; acetate-methanogenesis: $\text{CH}_3\text{COO}^- + \text{H}_2\text{O} \rightarrow \text{CH}_4 + \text{HCO}_3^-$; formate-methanogenesis: $4 \text{HCOO}^- + \text{H}^+ + \text{H}_2\text{O} \rightarrow \text{CH}_4 + 3 \text{HCO}_3^-$; and H_2 -acetogenesis: $4 \text{H}_2 + \text{H}^+ + 2 \text{HCO}_3^- \rightarrow \text{CH}_3\text{COO}^- + 4 \text{H}_2\text{O}$. The uncertainties are $\pm 10\%$.

pyrite oxidation and barite dissolution with a Rayleigh isotopic fractionation by microbial sulfate reduction was required (SOM). Such a mixture, composed of 30% SO_4^{2-} derived from the oxidation of pyrite by radiolytically produced oxidants (10) and 70% SO_4^{2-} derived from the dissolution of barite, produced an initial $\delta^{34}\text{S}$ value of 8.13‰ VCDT and a $\Delta^{33}\text{S}$ value of -0.0087‰ (SOM). The isotopic evolution from the initial 8.13‰ VCDT to the present observation (18.63‰ VCDT for total dissolved S species) requires a Rayleigh fractionation process in which 70% of the initial SO_4^{2-} was removed as microbially precipitated pyrite (SOM). By this model, the total HS^- formed by microbial sulfate reduction would be 4.35 mM [$1.52 \text{ mM} \times 70\%/30\% + 0.80 \text{ mM HS}^-$ (SOM)].

The Gibbs free energy for microbial redox reactions was calculated to provide additional constraints on the dominant respiratory pathway occurring in this fracture water. Sulfate reduction dominated the free-energy yields for a wide range of electron donor and acceptor combinations (Table 2). The free-energy yields for these reactions were much greater than the minimum requirement for synthesis of 1/3 of an adenosine triphosphate molecule by pumping one proton across the cell membrane ($\sim -20 \text{ kJ}$) (26). Among electron donors available for sulfate reduction and methanogenesis, H_2 yielded more free energy than acetate and formate, and H_2 -utilizing sulfate reduction yielded the highest free energy and energy flux (Table 2), suggesting that CO_2 -utilizing methanogens and acetogens cannot sustain as high a population density as sulfate reducers and therefore would be minor constituents of the community, as is observed in the clone libraries. The prominence of the free-energy flux for H_2 -utilizing sulfate reduction over other metabolic reactions is consistent with the depletion of $\delta^{34}\text{S}$ values of HS^- relative to SO_4^{2-} (27) and the physiological characteristics inferred from the dominant phylotype.

The in situ rate of microbial sulfate reduction was estimated to range from 0.22 to 1.45 nM year^{-1} , or from 5.5×10^{-18} to 3.6×10^{-17} moles per cell year^{-1} (assuming that all observed cells, 4×10^7 cells liter^{-1} , actively reduce SO_4^{2-}), based on the potential microbially produced sulfide [4.35 mM (SOM)] and fracture water residence time of ~ 3 or ~ 20 million years inferred from noble gas analysis. Such a rate is comparable to rates

reported in subsurface sediments (28) and to the estimated rate of radiolytic H_2 generation (10), but far less (4 to 5 orders of magnitude) than the maintenance energy demand of mesophilic sulfate reducers as determined in laboratory experiments (29) (SOM). The estimated in situ sulfate reduction rate, when combined with the experimental maintenance energy demand [$48 \text{ mol (g dry weight cell)}^{-1} \text{ year}^{-1}$] (29) and assuming 20 fg per cell, would support only 200 to 1600 cells liter^{-1} , which is far below the observed $\sim 4 \times 10^7$ cells liter^{-1} . If cells were constantly growing and dying, then the experimental sulfate reducer yield of 12.2 g of dry weight cell mol^{-1} (29), when combined with the in situ sulfate reduction rate, would correspond to cell turnover times of 45 to 300 years. The isotopic estimate of the long-term in situ microbial activity, however, is 10^9 to 10^{10} times less than the maximum substrate consumption rate (Table 2), which would seem to indicate that as-yet-unidentified factors play a role in restraining the microbial respiration.

The hot, reducing, gaseous water emanating from a fracture at 2.8 to 4.2 kmbs harbored a microbial community dominated by a single *Firmicutes* phylotype. The *Firmicutes* probably penetrated the Mponeng fracture zone at current depths during infiltration of paleomeiotic water between 3 and 25 million years ago and since then have relied on nonphotosynthetically derived H_2 and SO_4^{2-} converted from Archaean/Proterozoic pyrite/barite. Nutrient concentrations have remained much higher than observed in shallower crustal environments, suggesting that the deep crustal biosphere may be energy-rich, is not approaching entropic death, and is capable of sustaining microbial communities indefinitely by geological processes.
