Binary oxide systems

Selenium oxyanions

Pseudo-second-order kinetic model

X-ray absorption spectroscopy (XAS)

ABSTRACT

Removal of selenium oxyanions by the binary oxide systems, Al- or Fe-oxides mixed with X-ray noncrystalline SiO₂, was previously not well understood. This study evaluates the adsorption capacity and kinetics of selenium oxyanions by different metal hydroxides onto SiO₂, and uses X-ray absorption spectroscopy (XAS) to assess the interaction between selenium oxyanions and the sorbents at pH 5.0. The binary oxide systems of Al(III)- or Fe(III)-oxides mixed with SiO₂ were prepared, and were characterized for their surface area, point of zero charge (PZC), pH envelopes, X-ray diffraction analysis (XRD), and then macro-scale adsorption isotherm and kinetics of selenite and selenate, micro-scale adsorption XAS. The adsorption capacity of selenite and selenate on Al(III)/SiO₂ is greater than on Fe(III)/SiO₂. Adsorption isothermal and kinetic data of selenium can be well fitted to the Langmuir isotherm and pseudo-second-order kinetic models. Based on simple geometrical constraints, selenite on both the binary oxide systems forms bidentate inner-sphere surface complexes, and selenate on Fe(III)/SiO₂ forms stronger complexes than on Al(III)/SiO₂.

1. Introduction

Selenium (Se) is an essential micronutrient for humans and animals, but both Se toxicity and Se deficiency occur in different parts of the world (Frankenberger and Benson, 1994). Selenium can increase activity of the free hydroxyl radicals (OH·) that cause high oxidation stress harmful to living beings (Zhao et al., 2008). The essential or toxic character of Se in living beings depends not only on its concentration in the circumstances, but also on the chemical compound, which directly affects absorption and bioavailability (Mikkelsen et al., 1989; Lenz et al., 2008). Selenate and selenite are the dominant species in aqueous systems (Jacobs, 1989), however, selenite is easily adsorbed by soil minerals and a higher

concentration of selenate in industrial waste water is the major selenium compound polluting waters.

Aluminum, iron, and silica oxides are ubiquitous minerals in the earth's crust and they are usually employed in removing the pollutants in waters, because Al- and Fe-oxides have high surface areas and point of zero charge (i.e., 8–9.2) (Sparks, 2003). However, single oxide minerals are scarcer than binary oxide minerals in natural environments. The interaction of particles in binary oxide systems could influence the adsorption mechanism of adsorbents (Honeyman, 1984; Goh et al., 2008; Zhang et al., 2008). Lo and Chen (1997) and Kuan et al. (1998) showed that the adsorption capacity of selenium oxyanions on Al- and Fe-oxides coating quartz sands was about 1.1–1.5 mg Se per gram quartz. Kuan et al.

(2004) reported Al–Si complexation and precipitate forms on the amorphous SiO₂ surfaces, and discrete Fe(OH)₃ particles form in Fe(OH)₃/SiO₂ (Meng and Letterman, 1993, 1996). Therefore, it is necessary to study the adsorption capacities and mechanisms of selenate and selenite by the binary oxide systems, Al(III)- or Fe(III)-oxides mixed with X-ray non-crystalline SiO₂ surfaces.

X-ray absorption spectroscopic studies provide information to help understand the interaction between oxyanions and mineral surfaces, and this information can also improve both theoretical and practical understanding of surface complexation reactions (Sparks, 2003). Hayes et al. (1987) previously compared selenate and selenite adsorption on various mineral surfaces and showed that selenate generally formed relatively weakly-bound complexes, while selenite formed stronger complexes. The surface structure of Fe-oxides can strongly affect their surface chemistry and reactivity with oxyanions. For example, sulfate formed inner-sphere monodentate complexes on a hematite surface (Hug, 1997), but it can be formed as inner- and outer-sphere complexes on goethite (wijnja and Schulthess, 2000). However, since pH values can strongly affect surface properties of Fe-oxides and oxyanions, it is necessary to discuss the change of mineral surfaces and oxyanions at different pH values. Manseau and Charlet (1994) reported that the changes in surface structure of HFO, goethite, and akaganeite led to different ratios of edge and corner sharing surface complexes for arsenate, selenate, and selenite at acidic pH. Peak (2006) reported that adsorption mechanisms of selenium oxyanions on mineral surfaces are strongly influenced by sorbent surface properties, and observed that selenite forms outer- and inner-sphere complexes on hydrous aluminum oxides, while hydrous aluminum oxides form outer-sphere complexes with sulfate and selenate, but inner-sphere monodentate surface complexes are formed between sulfate and selenate and α -Al₂O₃. The overall conclusion is that selenite forms inner-sphere complexes on aluminum oxide minerals and selenate forms more outer- and less inner-sphere complexes. However, there have been few studies using XAS to examine the interactions of amorphous binary oxide systems and oxyanions.

The objectives of this study were to evaluate the adsorption capacity and kinetics of selenium oxyanions by the binary oxide systems, and to understand the interaction between selenium oxyanions and the adsorbents using XAS.

2. Materials and methods

2.1. Preparation and characterization of the binary oxide systems

The binary oxide systems of Al(III) or Fe(III) mixed with X-ray noncrystalline SiO₂ were carried out in 1-L polypropylene bottles (with caps). The silica (SiO₂) purchased from Cab-O-Sil M5 (Cabot Corp., Tuscolca, IL) was an X-ray noncrystalline and fine silica with BET surface area of $200 \pm 25 \text{ m}^2 \text{ g}^{-1}$ (Kuan et al., 2004). Before synthesis of the binary oxide systems, the suspension of SiO₂ was aged at 25 °C under an N₂ atmosphere for 24 h. The concentrations of binary oxide suspensions were $5 \times 10^{-3} \text{ M}$ for Al(NO₃)₃ or Fe(NO₃)₃ mixed with 1 g L^{-1} SiO₂ at

pH 5.0, monitoring with pH-stat (TIM865 Titration Manager, Radiometer Analytical). The suspensions of the binary oxide systems were synthesized at 25 °C for sorbents in the study, adjusted to the desired pH by NaOH and HNO₃ solutions, and shaken at 300 rpm for 24 h. After the synthesis process, a subsample collected from the suspension was centrifuged (Hitachi, 18PR-52) at $21,400 \times g$ for 15 min. The precipitate was washed several times with double deionized water (DDW) and freeze-dried (Millitorr Elemech FD-101) prior to X-ray and specific surface area analyses.

The precipitates prepared at various pH were characterized by X-ray diffraction (XRD). The samples were examined with an X-ray diffractometer (Rigaku Miniflex) using CuK α radiation generated at 30 KV and 15 mA. The specific surface area of the binary oxide systems was determined by a specific area (Micrometry, Tristar, FL), using the N₂-BET method. The Zetasizer (Malvern Zetasizer 3000 HS) was used to determine the PZC by the zeta potential function of pH in 0.01 M NaNO₃.

2.2. Adsorption experiments

All adsorption experiments were carried out at 25 °C, and the background electrolyte concentrations were 0.1, 0.01 and 0.001 M NaNO₃ solution, as monitored by pH-stat. Sample pH was adjusted by HNO₃ or NaOH for the entire reaction process. After all reactions, the suspensions were passed through a membrane filter (Millipore filter, 0.22 μm), and then the filtrates were analyzed by inductively coupled plasma atomic emission spectrometry (ICP-AES, Perkin Elmer, Optima 2000DV). The selenite solutions had already been analyzed by ion chromatography (IC), and we observed no selenite oxidizing to selenate during that operation. Besides that, our sample solutions were analyzed as soon as possible and all samples were kept in a 4 °C refrigerator. Our XANES results showed that no oxidizing occurs. Thus, analyzing the solutions by ICP-AES is more efficient.

2.3. Equilibrium adsorption

For the pH-edge experiment, the initial concentration of selenium oxyanions was 1 mM, and the pH of the binary oxide suspensions was maintained within the range of 2–10. The adsorption isotherm was studied by 0–3 mM selenium oxyanions reacted with the binary oxide systems at 25 °C and at pH 5 for 24 h. The isothermal results were fitted by Langmuir isotherm, described by Eq. (1):

$$Q_e = \frac{Q_m K_L C_e}{1 + K_L C_e} \quad (1)$$

where C_e is the equilibrium concentration (mg L^{-1}) in solution, Q_e is the amount of selenite and selenate adsorbed at equilibrium (mg g^{-1}), and K_L is the Langmuir constants related to adsorption capacity and energy of adsorption, respectively.

2.4. Adsorption kinetics

For adsorption kinetic experiments, the initial concentration of selenite was 1 mM, and selenate was 0.15 mM to react with the binary oxide systems, individually. The suspensions were set at pH 5.0 and shaken at 3000 rpm for 240 min. Subsamples

were taken at different times. The pseudo-second-order kinetic model can be solved with Eq. (2). The kinetic rate equation is expressed as follows:

$$dq_t/dt = k_2(q_{eq} - q_t)^2 \quad (2)$$

where q_{eq} is the sorption capacity at equilibrium and q_t is the solid-phase loading of selenium at time t . k_2 ($\text{g mg}^{-1} \text{h}^{-1}$) represents the pseudo-second-order rate constant for the kinetic model (Jang et al., 2003; Saha et al., 2004). By integrating Eq. (2) with the boundary conditions of $q_t = 0$ at $t = 0$ and $q_t = q_t$ at $t = t$, the following linear equation can be obtained:

$$\frac{t}{q_t} = \frac{1}{V_0} + \frac{1}{q_{eq}} t \quad (3)$$

$$V_0 = k_2 q_{eq}^2 \quad (4)$$

where V_0 ($\text{mg g}^{-1} \text{h}^{-1}$) is the initial sorption rate. Therefore, the V_0 and q_{eq} values of kinetic tests can be determined experimentally by plotting t/q_t versus t .

2.5. X-ray absorption spectroscopy analysis

Samples for XAS analysis were obtained by mixing the binary oxide systems suspensions with 10^{-3} M selenium oxyanions solution at pH 5.0 (adjusted by NaOH or HNO_3 solution) in 0.01 M NaNO_3 solution. After being shaken for 1 day, the sample suspensions were centrifuged at $21,400 \times g$ for 20 min, and the paste washed several times by DDW to remove excess salts. XAS data included X-ray absorption near-edge structures (XANES) and extended X-ray absorption fine structure (EXAFS) spectroscopy at the Se K-edge (12.658 keV) were collected on a Wiggler 20 beamline BL-17C at the National Synchrotron Radiation Research Center (NSRRC), Hsin-Chu, Taiwan. The electron storage ring operated at 1.5 GeV with a fixed current of 250 mA. The K-edge spectra of Se reacted with the binary oxide systems were recorded in transmission and fluorescence mode, respectively, and absorbance of the incident X-rays was collected by the ionization chambers I_t and I_f (Lytle Detector) (Lytle et al., 1984), separately. In order to attenuate scattered principle energy X-rays from entering the fluorescence detector, sollar slits, and an absorbing filter (As for Se atom) were placed between sample and I_f detector. The experiments were carried out from 12.63 to 12.70 keV at ambient temperature. In addition, the Au L_3 -edge spectrum was monitored by the I_f chamber simultaneously with I_t and I_f chambers, serving as the reference to calibrate energy shift due to monochromator drifts.

The XAS data was normalized with careful energy calibration by the standard strategies (Koningsberger and Prins, 1998). In addition, the IFEFFIT package, including Athena and Artemis was used for various data processing operations and analysis of the EXAFS spectra (Newville, 2001; Ravel and Newville, 2005). All of the XAS were normalized by Athena in the ifeffit package, transformed from electron energy to photoelectron wave number (k , $\text{\AA}^{-1}$) and weighted by k^3 to generate $k^3\chi(k)$ spectra to better demonstrate the contribution of different shells of the EXAFS oscillation function. Fourier transformation (FT) was further processed to produce radial

structure functions (RSF). The FEFF8.2 program (Cernohorsky, 1960; Rehr and Albers, 2000; Ankudinov et al., 1998) was employed to create theoretical phases and amplitude functions representing photoelectron scattering paths of Se-O by inputting standard structure parameters of reference Na_2SeO_4 and NaHSeO_3 from the Inorganic Crystallography Standard Databases (Inorganic Crystal Structure Database, 1981). The model fitting was conducted by the Artemis program, producing structure parameters such as coordination number (CN), interatomic distance (R), and Debye–Waller factor (σ^2). The phase and amplitude shift of EXAFS spectra between local structure of the experimental sample and the theoretical atomic model were adjusted by Debye–Waller factors and amplitude reduction factor. A fixed value of 0.85 was used for the global amplitude reduction factor (S_0^2).

3. Results and discussion

3.1. Characterization of the binary oxide systems

X-ray diffraction patterns show that both Al(III)/ SiO_2 and Fe(III)/ SiO_2 are X-ray noncrystalline mixed oxides at pH 5.0. The BET surface area of Al(III)/ SiO_2 is decreased to less than that of X-ray noncrystalline silica oxide (SiO_2), however, that of Fe(III)/ SiO_2 is increased (Table 1). Stumm and Wollast (1990) reported that a surface-coordinated metal ion, such as Cu(II) or Al(III), can block an oxide surface group, and the passive Al hydroxide inhibited the corrosion of the $\text{SiO}_{2(s)}$ surface by OH^- ions, Al-oxide particles may block the surface pores of silica oxide. Meng and Letterman (1993, 1996) reported discrete $\text{Fe}(\text{OH})_3$ particles formed in $\text{Fe}(\text{OH})_3/\text{SiO}_2$, and discrete $\text{Fe}(\text{OH})_3$ particles increase the total surface area of the binary oxide systems. The surface charge of both binary oxide systems decreases with increasing pH value because of increasing OH^- ions (Fig. 1). The zeta potential of Fe(III)/ SiO_2 is less than Al(III)/ SiO_2 , and Meng and Letterman (1993) reported the zeta potential of Fe(III)/ SiO_2 as the overall results contributed by negatively charged SiO_2 and positively charged $\text{Fe}(\text{OH})_3$. The silicate adsorption on $\text{Fe}(\text{OH})_3$ may decrease the surface potential of $\text{Fe}(\text{OH})_3$. Stumm (1992) reported that the pH_{zpc} range of aluminum and iron oxides is 7.8–9.1, however, the interaction of Al with amorphous silica suggests Al has covered the SiO_2 particles, and the negative silica sites could not cause the pH_{zpc} of Al(III)/ SiO_2 to be less than 9.1 (Kuan et al., 2004), thus the pH_{zpc} of the Fe(III)/ SiO_2 system is lower than Al(III)/ SiO_2 .

Table 1 – The surface area and pore size of the binary oxide systems synthesized at pH 5.0 and X-ray noncrystalline silica oxide.

System	BET surface area ($\text{m}^2 \text{g}^{-1}$)	Average pore size (nm)
Al(III)/ SiO_2 , pH 5.0	157	36
Al(III)/ SiO_2 , pH 8.0	188	29
Fe(III)/ SiO_2 , pH 5.0	249	22
Fe(III)/ SiO_2 , pH 8.0	247	21
The BET surface area of SiO_2 is $200 \text{ m}^2 \text{g}^{-1}$ (Kuan et al., 2004).

3.2. Equilibrium adsorption

3.2.1. pH-adsorption envelopes

For Al(III)/SiO₂ and Fe(III)/SiO₂ prepared at 25 °C, pH 5.0, the amount of selenium oxyanions adsorbed by the binary oxide systems surface is dependent on the anionic characteristics and the type of adsorption sites. To determine the optimum

pH for adsorption of selenium over the binary oxide systems, adsorption of selenium oxyanions as a function of pH was studied. Removal of selenium in the range of pH 2–12 is shown in Fig. 2. The removal selenium efficiencies of both binary oxide systems decreases with increasing pH value. However, the amphoteric effect of aluminum and negative surface charge of SiO₂ reduce the amounts of removal selenium oxyanions amount in the Al(III)/SiO₂ system at pH < 4.0. When the pH value is increased, the OH[−] ions can compete with selenium oxyanions for fixed surface adsorption sites. The highest removal efficiency of selenite and selenate for both binary oxide systems is around pH 4.0, while Al³⁺ is dissolved in the range of pH < 4.0. Ghosh et al. (1994) observed the removal was 100% at a pH of 5.5 or less for all initial concentrations of selenite on hydrous alumina, and virtually all of the selenite was adsorbed, even at pHs higher than the PZC (8.1) of alumina. However, the adsorption of selenate was more strongly dependent on pH than that of selenite. Jordan et al. (2009a) reported sorption of selenite onto magnetite decreases when the pH increases. Jordan et al. (2009b) reported that selenite adsorption onto hematite depended on the pH of the suspension, and the maximum sorption of selenite is in the acidic pH range. Sorption of selenite onto hematite decreases with increasing pH.

At any given pH value, both the binary oxide systems have higher affinities for selenite than for selenate, and the selenium oxyanion removal capacity of the binary oxide systems is strongly influenced by the surface charge and the environmental pH. This is consistent with the results derived from

Fig. 2 – The pH adsorption edge of (a) selenite, (b) selenate on Al(III)/SiO₂ and (c) selenite, (d) selenate on Fe(III)/SiO₂ at pH 5.0 in different concentration of the background electrolytes.

distinguishing various anion affinities based on the first acidity constant (Hayes, 1987; Hayes et al., 1988). Furthermore, removal of selenite remained effective when the system pH is high, suggesting that strong complexation occurs between selenite and both binary oxide surfaces.

The pH adsorption envelope of selenate on both binary oxide systems is affected by the concentration of the background electrolyte, as shown by experimental evidence, but selenite is not. The selenite and selenate adsorption by Fe-oxides both formed inner-sphere complexes, which was provided by the EXAFS (Hayes et al., 1988). There is no doubt that selenium adsorption on Fe(III)/SiO₂ is not influenced by the electrolyte solutions. Peak and Sparks (2002) indicated that selenate forms only inner-sphere surface complexes on hematite but forms a mixture of outer- and inner-sphere surface complexes on goethite and HFO. The selenate adsorption mechanism is strongly affected by both pH and ionic strength. Although the adsorption envelope of both selenite and selenate are dependent on electrolyte concentration for the Al system in previous studies, Ghosh et al. (1994) observed the removal was 100% at a pH of 5.5 or less for all initial concentrations of selenite on hydrous alumina. At very low ratios, virtually all of the selenite was adsorbed, even at pHs higher than the PZC (8.1) of alumina. And the adsorption of selenate was more strongly dependent on pH than that of selenite. Peak (2006) and Peak et al. (2006) reported that selenite adsorption by hydroxyaluminum and hydroxyaluminosilicate formed both inner-sphere and outer-sphere complexes, selenate formed outer-sphere complexes with hydroxyaluminum, and selenate formed inner-sphere complexes with α -Al₂O₃. It may be argued that selenium adsorption by Al(III)/SiO₂ formed outer-sphere or inner-sphere complexes. However, selenium adsorption may be influenced by the electrolyte solutions in Al(III)/SiO₂. From our EXAFS results, selenite on Al(III)/SiO₂ formed inner-sphere complexes. Although Fig. 2 showed that selenite adsorption on Al(III)/SiO₂ was affected by electrolyte concentrations in the range of pH 4–6, the effect was not significant with increasing pH. Hayes (1987) reported that selenite adsorbed onto the adsorbent, goethite (α -FeOOH), forms an inner-sphere complex, and selenate forms a weak outer-sphere, and then selenate on adsorbents is affected by lyotropic effect in the electric double layer theory. Fig. 2 shows that the removal efficiencies of selenite and selenate on Al(III)/SiO₂ are greater than on Fe(III)/SiO₂ in the Al(III)/SiO₂ system. When the basic solution was added into the Al(III)/SiO₂ system, Al formed complexes with SiO₂ to increase the adsorption sites on the negatively charged surface of SiO₂. Thus a pH 5.0 and 0.01 M electrolyte solution was chosen for isothermal, kinetics, and desorption experiments.

3.2.2. Adsorption isotherms

To investigate the adsorption capacity, a series of selenite and selenate solutions were shaken with both the binary oxide systems that were prepared at pH 5.0 for 24 h. Adsorption data is fitted by Langmuir isotherm well ($r^2 > 0.858$, $P < 0.01$ ($n = 7$)) (Fig. 3, Table 2). The correlation coefficients suggest that the Langmuir isotherm model is suitable for describing the adsorption equilibrium of selenite and selenate by the binary oxide systems. The fitting data shows that the maximum

Fig. 3 – Adsorption isotherms of (a) selenite and (b) selenate on the binary oxide systems at pH 5.0, 25 °C in 0.01 M NaNO₃ as background electrolytes.

adsorption capacity ($Q_{\max}$) for selenite and selenate by Al(III)/SiO₂ was 32.7 and 11.3 mg/g, and the $Q_{\max}$ for selenite and selenate by Fe(III)/SiO₂ are 20.4 and 2.4 mg g⁻¹, respectively. In consideration of the adsorption capacities for selenium species, Al(III)/SiO₂ and Fe(III)/SiO₂ appear to be much higher than coarse Al- or Fe-oxide coated sand (Lo and Chen, 1997;

Table 2 – The isotherm adsorption parameters of selenite and selenate on the binary oxide systems at pH 5.0 for the Langmuir isothermal fitting model.

System	Adsorbate	K_L (L mg g ⁻¹) ^a	$Q_{\max}$ (mg g ⁻¹) ^b	r^2

^a Langmuir constants (L mg g⁻¹).

^b The maximum adsorption capacity (mg g⁻¹).

** $P < 0.01$ ($n = 7$).

Kuan et al., 1998). Both of the binary oxide systems can be attributed to fine particles that increase the contact between selenium species and the adsorbents.

The adsorption capacity of selenite on both binary oxide systems is more than selenate, which is consistent with the results derived from distinguishing various anion affinities based on the first acidity constant (Hayes, 1987; Hayes et al., 1988). The chemical characteristics and the geometry structure of selenite are similar to phosphate, whereas selenate is similar to sulfate (Hayes, 1987; wijnja and Schulthess, 2000), and adsorbed selenite on the both binary oxide systems is greater than selenate.

The Al(III)/SiO₂ system shows a much greater capacity for selenite and selenate compared with the Fe(III)/SiO₂ system, resulting from high affinity of the more positive charge of the Al(III)/SiO₂ system for selenium oxyanions (Fig. 1). The precipitation of iron particles on SiO₂ cannot increase any adsorption site, and the negatively charged surface of SiO₂ increases the repulsion between selenium oxyanions and SiO₂. Thus the $Q_{\max}$ of selenium on Al(III)/SiO₂ is much higher than that of Fe(III)/SiO₂ (Table 2). As for the mechanisms by which selenite and selenate are adsorbed on the binary oxide systems, previous spectroscopic studies show that selenium is adsorbed to Al- and Fe-oxides by forming inner-sphere surface complexes by ligand exchange with hydroxyl groups at the mineral surface (Peak, 2006). To study the mechanism of the adsorption process, we subjected the samples to XANES and EXAFS spectra of selenium adsorbed to the binary oxide systems.

3.3. Adsorption kinetics

The kinetics of adsorption that describe the solute adsorption rate governing the residence time of the sorption reaction is one of the important characteristics that define the efficiency of adsorption. Fig. 4 shows the adsorption data of selenium by the both binary oxide systems at different time intervals and the simulation of the pseudo-second-order kinetic model. Adsorption of both selenite and selenate on the binary oxide systems approach pseudo-equilibrium more rapidly than those on Al or Fe coatings on quartz sands (Lo and Chen, 1997; Kuan et al., 1998). For selenite on Al(III)/SiO₂ and Fe(III)/SiO₂, 95% removal of selenite was achieved within 2 h of contact, and the adsorption equilibrium was approached (Fig. 4a). The removal percentage for selenate individually reached 99 and 96% on Al(III)/SiO₂ and Fe(III)/SiO₂ in 30 min, and the adsorption approached equilibrium too (Fig. 4b). The greater surface area and smaller particle size of both binary oxide systems raise the probability of the adsorption reactions. The kinetics data has been fitted by the zero-, first-, pseudo-second-, second-order, parabolic, and Elovich models, evaluating the r^2 and P-value, and the total fitted data was not shown. The pseudo-second-order kinetic model is the best model to describe the kinetic data in the binary oxide systems. Table 3 shows the determination coefficients (r^2) and the other parameters obtained from the pseudo-second-order kinetic model by the plot of t versus t/q_t to determine the V_0 and q_{eq} values for all the media. The pseudo-second-order model fits the kinetic data of the both binary oxide systems very well ($r^2 > 0.999$, $P < 0.001$, $n = 18$). The initial adsorption rate of

Fig. 4 – Adsorption kinetics of (a) selenite and (b) selenate on the binary oxide systems at pH 5.0, at 25 °C in 0.01 M NaNO₃ as background electrolytes.

selenite over Al(III)/SiO₂ is 6.25 mg g⁻¹ h⁻¹, which is less than that of selenate (57.5 mg g⁻¹ h⁻¹), and the rate of selenite and selenate over Fe(III)/SiO₂ is 8.36 and 4.89 mg g⁻¹ h⁻¹. The fitting data shows that Al(III)/SiO₂ has a higher affinity for selenate, and the adsorption capacity of selenate is greater than selenate on Fe(III)/SiO₂. Unlike selenite, in which the supernatant pH is stable, the pH increases from 5.0 to 8.0 for the selenate

Table 3 – Kinetic parameters of a pseudo-second-order kinetic model fitting selenium oxyanions adsorption by the binary oxide systems at pH 5.0.

equilibrium solution, indicating that hydroxide ions are released in the adsorption process. Since selenite strongly bonds to the metal oxide surface via the formation of stronger inner-sphere complexes, selenite takes more time to reach

equilibrium in the slow process (Balistrieri and Chao, 1987; Hayes, 1987; Neal et al., 1987; Zhang and Sparks, 1990; Scott and Morgan, 1996).

3.4. XAS data analysis

From the adsorption reaction of the XANES, there is no change in oxidation state following interaction between the selenium species and the binary oxide systems. Fig. 5 and Table 4 show the results of Se K-edge EXAFS conducted on samples of selenite adsorbed on the binary oxide systems at pH 5.0. The radial structure functions (RSFs) of the Fourier-transformed data are shown in Fig. 5a,b. In all the selenite samples, there is clear evidence of two shells in the RSFs: a first shell Se-O (fitted with 3O at 1.72 Å) and a second shell Se-Al or Se-Fe in both binary oxide systems (Fig. 5a). The Se-O distance is in good agreement with previous EXAFS experiments conducted on selenite, which have shown Se-O bond distances of 1.68–1.72 Å for aqueous and adsorbed selenite (Manceau and Charlet, 1994; Peak et al., 2006; Peak, 2006). Based on simple geometrical constraints, the best assignment of the bonding environment for selenite on Al(III)/SiO₂ (Se-Al was fitted with 2 Al at 3.22 Å) at pH 5.0 is a bidentate-binuclear surface complex (the range of the bond length is ~3.2 Å). This is in good agreement with previous studies (Hayes et al., 1987) of selenite adsorption on other aluminum-bearing mineral surfaces, which also reported bidentate-binuclear surface complexation. The presence of inner-sphere selenate on goethite is consistent with the work of Manceau and Charlet (1994), and they reported a similar Se-Fe bond distance of 3.29 Å, as compared to 3.31 Å in this work (Table 4). On hydrous ferric oxide (HFO), however, they found that their data were best described with 0.4 Fe at 2.80 Å and 1.8 Fe at 3.29 Å. They attributed the distance of 2.80 Å to a bidentate mononuclear surface complex and the distance of 3.29 Å to that of a bidentate-binuclear surface complex. The result of selenite on Fe(III)/SiO₂ shows the distance of 3.05 Å to form a bidentate mononuclear surface complex.

The local structure of selenate on the binary oxide systems was conducted by EXAFS fitting (Table 4 and Fig. 5b). In all the selenate samples, the first shell, Se-O, in the RSFs (fitted with 4O at 1.66 Å) is consistent with

Table 4 – Structure parameters of selenium chemicals and selenium oxyanions adsorbed on the binary oxide systems derived from the EXAFS spectrum fitting.

Sample	S_0^a	1st shell: Se-O			2nd shell: Se-metal		
		R (Å) ^b	CN ^c	σ^2 (Å ²) ^d	R (Å)	CN	σ^2 (Å ²)

previously published Se–O distances of aqueous and adsorbed selenate (Hayes et al., 1987; Peak and Sparks, 2002). The bonding length and coordination number (3.32 Å and CN = 1) of the Se–Al distance in the selenate sorption samples suggest that the coordination environment of selenate on the Al(III)/SiO₂ surface is an inner-sphere surface complex in the study. However, the Se–Fe bond length (3.04 Å) shows that selenate on Fe(III)/SiO₂ forms bidentate mononuclear complexes (Hug, 1997; Peak and Sparks, 2002). The EXAFS fitting data shows that selenate binding to Fe(III)/SiO₂ is stronger than to Al(III)/SiO₂. According to the EXAFS principles, the surrounding atoms at a distance from the X-ray absorbing atom is the bond distance. The longer the bond distance is, the weaker the interaction between the center and surrounding atoms. The Se–metal bond distances for selenite and selenate for the Fe(III)/SiO₂ system are virtually identical. The fit quality estimated accuracy of bond distances is ± 0.02 Å. Peak and Sparks (2002) indicated selenate forms only inner-sphere surface complexes on hematite but forms a mixture of outer- and inner-sphere surface complexes on goethite and HFO. The EXAFS results showed that selenate on Fe(III)/SiO₂ formed inner-sphere complexes. Although both selenate and selenite form inner-sphere complexes on the binary oxide systems at pH 5.0, the data suggests that selenite on the binary oxide systems forms stronger surface complexes than selenate.

4. Conclusions

According to the results, we suggest that Al- or Fe-oxide can modify the negative surface charge of SiO₂ in the binary oxide systems, and apply the binary oxide systems to anion adsorption, selenium oxyanions. From this study, we observed that Al(III)/SiO₂ and Fe(III)/SiO₂ are efficient at removing selenium oxyanions from aqueous solutions. However, the stronger association between Al(III) and the SiO₂ surface causes the overall surface charge to be more positive than Fe(III)/SiO₂, and the selenium adsorption capacity of Al(III)/SiO₂ to be more than Fe(III)/SiO₂. At pH 5.0, selenite on Al(III)/SiO₂ and Fe(III)/SiO₂ forms inner-sphere complexes, including bidentate and monodentate ones, respectively. However, selenate on Al(III)/SiO₂ forms weaker inner-sphere monodentate complexes, the same as selenate on Fe(III)/SiO₂. According to the bond distance of selenate, the higher affinity between selenate and Fe causes the shorter bond distance. The findings obtained in the present study are of fundamental significance in advancing the frontiers of knowledge on geochemistry of the binary oxide systems.
